1 Introduction

1.1 What do we care about?

Things chemistry/materials-related:

- What are the properties of atoms?
- What molecules do they make? What other substances do they make?
- What are the shapes of those molecules? Structures of those solids? Properties of them?
- How do those substances react with each other?
- What are the energies of those reactions?
- What are the rates of those reactions?
- What is the strongest substance?
- How do we make a substance to do...?
- add your own questions...

Things that relate to the *chemical* properties of substances.

1.2 How are we going to figure these out? With only a computer?

1926 Erwin Schrödinger equation: $\hat{H}\Psi = E\Psi$

1929 Paul Dirac, British physicist

The fundamental laws necessary for the mathematical treatment of a large part of physics and the whole of chemistry are thus *completely known*, and the difficulty lies only in the fact that application of these laws leads to equations that are *too complex to be solved*.

It therefore becomes desirable that *approximate practical methods* of applying quantum mechanics should be developed, which can lead to an explanation of the main features of complex atomic systems without too much computation.

1930's-1950's Elaboration, analytical applications

1950's Computers start to appear for technical applications

1960's Density functional theory emerges.

1960's-1970's Numerical solutions of Schrödinger equation for atoms/molecules—expert users

1980's “Supercomputer” era—routine use of computational chemistry software becomes possible

Figure 1: Ohio State Cray Y-MP supercomputer, ca. 1989. World’s fastest computer at the time. 333 MFlop top speed, 512 Mb RAM

1990's “Chemical accuracy” era—very precise solutions routinely available, for a cost! See [Schneider, JPC 1994](#).

1990's Density functional theory (DFT) allows applications to solids/surfaces/liquids to become common. See [Hass, Science, 1998](#)

1990's Visualization moves to the desktop

2000's Computational “screening,” materials discovery ([Gurkan, J. Phys. Chem. Lett., 2010](#)), materials genome (<https://materialsproject.org/>).

Today Computational chemistry widely integrated into all aspects of chemical, materials, biological research

Computational chemistry is now so vast it is impossible to cover everything completely. We limit ourselves to quantum-mechanics-based calculations.

1.3 Our goals

1. Understand when it is appropriate to use quantum-mechanics methods.
2. Be able to state the basic theoretical, mathematical, and numerical concepts behind quantum mechanical “wavefunction theory” (WFT) and “density functional theory,” (DFT) calculations.
3. Understand the terminology and practical issues associated with doing quantum chemical simulations.
4. Get hands-on experience with these concepts using popular computational tools of today, including GAMESS for molecular systems and Vasp for condensed phase systems.
5. Learn how to set up, execute, and analyze results in a modern, Python notebook environment.
6. Learn how to apply the results of quantum chemical simulations to calculate things you care about.
7. Demonstrate an ability to formulate a problem and apply QM methods to it.
8. Develop the skills to understand a literature paper in the area.

1.4 Reading resources

- These notes
- Chris Cramer, *Essentials of Computational Chemistry*, Wiley, 2004
- Martin, *Electronic Structure*, Cambridge, 2004
- Sholl and Steckel, *Density Functional Theory: A Practical Introduction*, Wiley, 2009

1.5 Software tools

1.5.1 Notebooks

- [jupyter](#)/ipython
- [emacs](#)/org-mode

1.5.2 Molecular methods

- Avogadro environment http://avogadro.cc/wiki/Main_Page
- GAMESS code <http://www.msg.ameslab.gov/GAMESS/GAMESS.html>

1.5.3 Supercell methods

- Vasp code <http://www.vasp.at/>
- ASE environment <https://wiki.fysik.dtu.dk/ase/>

1.5.4 Great for getting started

- Webmo <http://www.webmo.net/>

2 Refresher on Quantum Mechanics

2.1 Why quantum mechanics?

Want to describe “mechanics” (equations of motion) of atomic-scale things, like electrons in atoms and molecules

Why? These ultimately determine the energy, the shape, and all the properties of matter.

de Broglie wavelength (1924)

$$\lambda = h/p = h/mv \quad (1)$$

$$h = 6.626 \times 10^{-34} \text{ J s (Planck's constant)} \quad (2)$$

	Car	Electron
mass m	1000 kg	9.1×10^{-31} kg
velocity v	100 km/hr	0.01 c
	typical value on the highway	typical value in an atom
momentum p	2.8×10^{-4} kg m/s	2.7×10^{-24} kg m/s
wavelength λ	2.4×10^{-38} m	2.4×10^{-10} m
	too small to detect. Classical!	Comparable to size of an atom.
		<i>Must treat with QM!</i>

How to describe wave properties of an electron? Schrödinger equation (1926)

$$\text{Kinetic energy} + \text{Potential energy} = \text{Total Energy}$$

Expressed as differential equation (Single particle, non-relativistic):

$$-\frac{\hbar^2}{2m} \nabla^2 \Psi(\mathbf{r}, t) + V(\mathbf{r}, t) \Psi(\mathbf{r}, t) = -i\hbar \frac{\partial}{\partial t} \Psi(\mathbf{r}, t) \quad (3)$$

If the potential V is time-invariant, can use separation of variables to show that the steady-state, time-independent solutions are characterized by an energy E and described by:

$$-\frac{\hbar^2}{2m} \nabla^2 \psi(\mathbf{r}) + V(\mathbf{r}) \psi(\mathbf{r}) = E \psi(\mathbf{r}) \quad (4)$$

$$\Psi(\mathbf{r}, t) = \psi(\mathbf{r}) e^{-iEt/\hbar} \quad (5)$$

2.2 Postulates of non-relativistic quantum mechanics

2.3 Notes on constants and units

Resource on physical constants: <http://physics.nist.gov/cuu/Constants/> Resource for unit conversions: <http://www.digitaldutch.com/unitconverter/>

Unit converter available in Calc mode in [Gnu emacs](#) **highly recommended**

$$\text{Energy units } 1 \text{ eV} = 1.60218 \times 10^{-19} \text{ J} = 96.485 \text{ kJ/mol} = 8065.5 \{ \text{cm}^{-1} \} = 11\,064 \text{ K } k_B$$

Table 1: Postulates of Non-relativistic Quantum Mechanics**Postulate 1: The physical state of a system is completely described by its wavefunction**

Ψ . In general, Ψ is a complex function of the spatial coordinates and time. Ψ is required to be:

- I. Single-valued
- II. continuous and twice differentiable
- III. square-integrable ($\int \Psi^* \Psi d\tau$ is defined over all finite domains)
- IV. For bound systems, Ψ can always be normalized such that $\int \Psi^* \Psi d\tau = 1$

Postulate 2: To every physical observable quantity M there corresponds a Hermitian operator \hat{M} . **The only observable values of M are the eigenvalues of \hat{M} .**

Physical quantity	Operator	Expression
Position x, y, z	$\hat{x}, \hat{y}, \hat{z}$	x, y, z
Linear momentum p_x, \dots	\hat{p}_x, \dots	$-i\hbar \frac{\partial}{\partial x}, \dots$
Angular momentum l_x, \dots	\hat{p}_x, \dots	$-i\hbar \left(y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y} \right), \dots$
Kinetic energy T	\hat{T}	$-\frac{\hbar^2}{2m} \nabla^2$
Potential energy V	\hat{V}	$V(\mathbf{r}, t)$
Total energy E	\hat{H}	$-\frac{\hbar^2}{2m} \nabla^2 + V(\mathbf{r}, t)$

Postulate 3: If a particular observable M is measured many times on many identical systems in a state Ψ , the average results will be the expectation value of the operator \hat{M} :

$$\langle M \rangle = \int \Psi^* (\hat{M} \Psi) d\tau$$

Postulate 4: The energy-invariant states of a system are solutions of the equation

$$\begin{aligned} \hat{H} \Psi(\mathbf{r}, t) &= i\hbar \frac{\partial}{\partial t} \Psi(\mathbf{r}, t) \\ \hat{H} &= \hat{T} + \hat{V} \end{aligned}$$

The time-independent, stationary states of the system are solutions to the equation

$$\hat{H} \Psi(\mathbf{r}) = E \Psi(\mathbf{r})$$

Postulate 5: (The uncertainty principle.) Operators that do not commute ($\hat{A}(\hat{B}\Psi) \neq \hat{B}(\hat{A}\Psi)$) are called *conjugate*. Conjugate observables cannot be determined simultaneously to arbitrary accuracy. For example, the standard deviation in the measured positions and momenta of particles all described by the same Ψ must satisfy $\Delta x \Delta p_x \geq \hbar/2$.

Table 2: Atomic units common for quantum mechanical calculations (see http://en.wikipedia.org/wiki/Atomic_units)

	Atomic unit	SI unit	Common unit
Charge	$e = 1$	$1.6021 \times 10^{-19} \text{ C}$	
Length	$a_0 = 1 \text{ (bohr)}$	$5.291 77 \times 10^{-11} \text{ m}$	$0.529 177 \text{ \AA}$
Mass	$m_e = 1$	$9.109 38 \times 10^{-31} \text{ kg}$	
Angular momentum	$\hbar = 1$	$1.054 572 \times 10^{-34} \text{ J s}$	
Energy	$E_h = 1 \text{ (hartree)}$	$4.359 744 \times 10^{-18} \text{ J}$	27.2114 eV
Electrostatic force	$1/(4\pi\epsilon_0) = 1$	$8.987 552 \times 10^{-9} \text{ N m}^2/\text{C}^2$	
Boltzmann constant		$1.380 65 \times 10^{-23} \text{ J/K}$	$8.617 33 \times 10^{-5} \text{ eV/K}$

2.4 Example: Energy states of a particle in a box

System defined by potential experienced by particle:

$$V(\mathbf{r}) = 0, \quad 0 < x, y, z < L$$

$$V(\mathbf{r}) = \infty, \quad x, y, z \leq 0, \quad x, y, z \geq L$$

3D box \rightarrow 3 degrees of freedom/coordinates

Schrödinger equation

$$-\frac{\hbar^2}{2m_e} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi(x, y, z) = E\psi(x, y, z) \quad (6)$$

$$\psi(x, y, z) = 0, \quad x, y, z \leq 0, \quad x, y, z \geq L \quad (7)$$

A second-order, linear, partial differential equation. Boundary value problem. Solve by separation of variables. Postulate $\psi(x, y, z) = X(x)Y(y)Z(z)$. Substituting and rearrange to get

$$-\frac{\hbar^2}{2m_e} \left(\frac{1}{X(x)} \frac{\partial^2 X(x)}{\partial x^2} + \frac{1}{Y(y)} \frac{\partial^2 Y(y)}{\partial y^2} + \frac{1}{Z(z)} \frac{\partial^2 Z(z)}{\partial z^2} \right) = E \quad 0 < x, y, z < L \quad (8)$$

ftn x + ftn y + ftn z = constant \rightarrow each term must be constant.

Equation for each dimension

$$-\frac{\hbar^2}{2m_e} \frac{\partial^2 X(x)}{\partial x^2} = E_x X(x), \quad X(0) = X(L) = 0 \quad (9)$$

Seek function that twice differentiated returns itself and satisfies boundary conditions.

$$X(x) = \sin \frac{n_x \pi x}{L}, \quad n_x = 1, 2, 3, \dots \quad (10)$$

$$E_{n_x} = \frac{n_x^2 \pi^2 \hbar^2}{2m_e L^2} \quad (11)$$

Solutions called *eigenfunctions* (or *wavefunctions*) and *eigenvalues*. Characterized by *quantum numbers*, one for each degree of freedom. These (and all QM) solutions have certain special properties, including that they *orthonormal* and form a *complete set*.

Normalization

Seek a constant such that the inner eigenfunction product is unity.

$$C^2 \int_0^L \sin^2 \frac{n_x \pi x}{L} dx = C^2 L/2 = 1 \rightarrow C = \pm \sqrt{\frac{2}{L}} \quad (12)$$

$$X(x) = \pm \sqrt{\frac{2}{L}} \sin \frac{n_x \pi x}{L}, \quad n_x = 1, 2, 3, \dots \quad (13)$$

Orthonormal

$$\langle X_{n_x} | X_{n'_x} \rangle = \delta_{n_x, n'_x} \quad \text{Dirac notation} \quad (14)$$

- Energy increase with number of *nodes*.

- Is this real? See [Ho, J. Phys. Chem. B 2005, 109, 20657](#). Where is the electron?

Complete set Any function on the same domain that satisfies the same boundary conditions can be represented as a linear combination of these solutions:

$$f(x) = \sum_i \left\{ \int_0^L X_i(x) f(x) dx \right\} X_i(x) = \sum_i C_i X_i(x) \quad (15)$$

$$|f\rangle = \sum_i |X_i\rangle \langle X_i|f\rangle \quad \text{Dirac notation} \quad (16)$$

Illustrates idea of a basis set. These functions are the basis in “plane wave” supercell methods.

Three-dimensional solutions

$$\psi(x, y, z) = X(x)Y(y)Z(z) = \left(\frac{2}{L}\right)^{3/2} \sin \frac{n_x \pi x}{L} \sin \frac{n_y \pi y}{L} \sin \frac{n_z \pi z}{L}, \quad n_x, n_y, n_z = 1, 2, 3, \dots \quad (17)$$

$$E = E_x + E_y + E_z = \frac{(n_x^2 + n_y^2 + n_z^2) \pi^2 \hbar^2}{2mL^2} \quad (18)$$

Properties of solutions:

- Symmetry of system introduces degeneracy in solutions

Figure 2: Energy states of 3D Particle in a box

- Energy depends on volume \rightarrow pressure!

3 Hydrogen atom: simplest chemical “thing”

3.1 Schrödinger equation

Place massive nucleus at origin and describe position of electron in spherical coordinates

$$\left\{ -\frac{\hbar^2}{2m_e} \nabla^2 + V(r) \right\} \psi(\mathbf{r}) = E\psi(\mathbf{r}) \quad (19)$$

$$V(r) = -\frac{e^2}{4\pi\epsilon_0} \frac{1}{|\mathbf{r}|} \quad (20)$$

Coulomb potential—our nemesis! Decays slowly with distance. Boundary conditions?

3.2 Analytical solutions

1. Separate: $\psi(r, \theta, \phi) = R(r)\Theta(\theta, \phi)$
2. Angular equation $\hat{L}^2\Theta(\theta, \phi) = E_L\Theta(\theta, \phi)$
 - (a) $\Theta = Y_{lm_l}(\theta, \phi)$ are “spherical harmonics”, describe angular motion
 - (b) Azimuthal quantum number $l = 0, 1, \dots, n-1$, correspond to *s*, *p*, *d*, ... orbital sub-shells; angular “shape,” number of angular nodes, angular momentum of electron
 - (c) Magnetic quantum number $m_l = -l, -l+1, \dots, l$, ... orientation of orbital
3. Radial equation

$$\left\{ -\frac{\hbar^2}{2m_e} \frac{d}{dr^2} + \frac{\hbar^2 l(l+1)}{2m_e r^2} - \frac{e^2}{4\pi\epsilon_0} \frac{1}{r} \right\} rR(r) = ErR(r)$$

Solutions are a polynomial * exponential decay. Exponential part called a *Slater* function. Larger the exponent, faster the decay. Degree of polynomial determined by principle quantum number $n = 1, 2, \dots$

Energy expression, corresponds to our conventional H atom spectrum

$$E_n = -\frac{1}{n^2} \left(\frac{e^2}{2a_0} \right) = -13.6 \text{ eV} \cdot \frac{1}{n^2}, \quad n = 1, 2, \dots$$

Table 3: Hydrogen atom

$$\begin{aligned}
V(r) &= -\frac{e^2}{4\pi\epsilon_0} \frac{1}{r}, 0 < r < \infty \\
\hat{H} &= -\frac{\hbar^2}{2m_e} \left\{ \frac{1}{r^2} \left[\frac{\partial}{\partial r} r^2 \frac{\partial}{\partial r} \right] - \frac{\hat{L}^2}{\hbar^2 r^2} \right\} + V(r) \\
\hat{L}^2 &= -\hbar^2 \left[\frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) \right] \\
\psi(r, \theta, \phi) &= R(r) Y_{l, m_l}(\theta, \phi) \\
\left\{ -\frac{\hbar^2}{2m_e} \frac{d}{dr^2} + \frac{\hbar^2 l(l+1)}{2m_e r^2} - \frac{e^2}{4\pi\epsilon_0} \frac{1}{r} \right\} rR(r) &= ErR(r) \\
R_{nl}(r) &= N_{nl} e^{-x/2} x^l L_{nl}(x), \quad x = \frac{2r}{na_0} \\
P_{nl}(r) &= r^2 R_{nl}^2 \\
n &= 1, 2, \dots, \quad l = 0, \dots, n-1 \quad m_l = 0, \pm 1, \dots, \pm l \\
N_{nl} &= \sqrt{\left(\frac{2}{na_0} \right)^3 \frac{(n-l-1)!}{2n(n+l)!}} \\
L_{10} &= L_{21} = L_{32} = \dots = 1 \quad L_{20} = 2 - x \quad L_{31} = 4 - x \\
E_n &= -\frac{1}{2} \frac{\hbar^2}{m_e a_0^2} \frac{1}{n^2} = -\frac{E_H}{2} \frac{1}{n^2} \\
|L| &= \hbar \sqrt{l(l+1)}, L_z = m_l \hbar \\
\langle r \rangle &= \left\{ \frac{3}{2} n^2 - \frac{1}{2} l(l+1) \right\} \frac{a_0}{Z}
\end{aligned}$$

Questions: Ionization energy of an H atom? $1s \rightarrow 2s$ energy? Thermal populations?

Integrate out angular components to get radial probability function $P_{nl}(r) = r^2 R_{nl}^2(r)$

$$\langle r \rangle = \int r P_{nl}(r) dr = \left(\frac{3}{2} n^2 - l(l+1) \right) a_0$$

Note darn electron doesn't want to stay in the Coulomb well! Wavefunction extends beyond the classical region defined by $E_n = V(r_{\text{classical}})$. This phenomenon is called *tunneling*, is a purely quantum mechanical effect, is pervasive in chemistry, leading for instance to chemical bonding.

Figure 3: H atom wavefunctions

Figure 4: H atom radial probability

3.3 Variational principle

What if we don't know where to look to find the $R(r)$? Or an analytical solution doesn't exist? Solve numerically.

$l = 0$ case, in atomic units:

Figure 5: Pythonic s ($l = 0$), p ($l = 1$), and d ($l = 2$) spherical harmonics. Color scale from red to white to blue corresponds to positive to zero to negative sign of wavefunction.

$$\left\{ -\frac{1}{2} \frac{d^2}{dr^2} - \frac{1}{r} \right\} rR(r) = ErR(r), \quad 0 < r < \infty$$

Guess something. Must obey appropriate boundary conditions and be a well-behaved function. For example, a *Gaussian*:

$$g_\xi(r) = e^{-\xi r^2}$$

Let's normalize:

$$N = \left\{ \int_0^\infty g_\xi^2(r) r^2 dr \right\}^{-1/2} = 2 \left(\frac{8\xi^3}{\pi} \right)^{1/4}$$

$$\tilde{g}_\xi(r) = Ng_\xi(r)$$

Now evaluate energy, say for $\xi = 1$:

$$\langle E \rangle = \langle \tilde{g}_1 | \hat{H} | \tilde{g}_1 \rangle = -0.096 \text{ Hartree}$$

Hmmm, not very good, much higher in energy than true answer of -0.5 Hartree.

Let's try adding two Gaussians together, with equal weight:

$$b(r) = N_s (\tilde{g}_1(r) + \tilde{g}_{0.5}(r))$$

Normalize:

$$\langle b(r) | b(r) \rangle = N_s^2 (\langle \tilde{g}_1 | \tilde{g}_1 \rangle + \langle \tilde{g}_{0.5} | \tilde{g}_{0.5} \rangle + 2\langle \tilde{g}_1 | \tilde{g}_{0.5} \rangle) \quad (21)$$

$$= N_s(1 + 1 + 2S) = 1 \quad (22)$$

$$N_s = \frac{1}{\sqrt{2(1+S)}} \quad (23)$$

Note appearance of “overlap integral” $S = \langle \tilde{g}_1 | \tilde{g}_{0.5} \rangle$, shows how similar or different g_i are.

Re-evaluate energy

$$\langle b(r) | \hat{H} | b(r) \rangle = -0.306 \text{ Hartree}$$

Much closer to the truth!

Could even weight the two Gaussians differently:

$$c(r) = N'_s (\tilde{g}_1(r) + 1.5\tilde{g}_{0.5}(r))$$

$$\langle c(r) | \hat{H} | c(r) \rangle = -0.333 \text{ Hartree}$$

Better yet!

Figure 6: Comparison of exact and approximations 2 H 1s radial function

Could continue to add Gaussians of various exponents, and could vary weights, or could even add in any other functions that we want that are “well-behaved.” Would find that no matter what we do, the “model” energy would be greater than the “true” value. Basis of the *variational principle*:

For any system described by the Hamiltonian \hat{H} and any satisfactory trial wavefunction Ψ ,

$$E = \frac{\langle \Psi | \hat{H} | \Psi \rangle}{\langle \Psi | \Psi \rangle} \geq E_0$$

where E_0 is the true ground state energy of the system.

Consequence of the completeness of the solutions of the Schrödinger equation. Extremely important to us, because we can use the *calculus of variations* to seek energy-optimal Ψ .

3.4 Basis functions

Recognize that we are approximating

$$R_{10}(r) \approx f(r) = \sum_i c_i \phi_i(r)$$

ϕ_i are *basis functions* and c_i are *variational parameters*, or *coefficients*.

If we find c_i that minimize energy, then we have an optimal approximation to E_0 within our basis, and we are sure that E_0 is an upper bound on the truth. Adding more basis functions /must/ lower energy.

Common trade-offs:

1. Want to choose ϕ_i that are good approximation to the “truth”
2. Want to choose ϕ_i that are mathematically convenient

Slaters	Gaussians	Plane waves	Mixed basis
Accurate	Moderate accuracy	Poor accuracy	
Expensive	modest cost	cheap!	
ADF	Gaussian, GAMESS, NWChem, Qchem	Vasp, CPMD, QuantumEspresso	FLAPW, CP2k

Virtually *all* quantum codes work on this principle, and the main differences are in details of implementation and ancillary functionality provided.

There are exceptions. *GPW* for instance solves the QM equations by finite difference expressions on a numerical grid. Lends itself to parallelization and may be the future...remains to be seen!

3.5 Secular equations

Apply variational principle to two basis functions for the H atom:

$$f(r) = c_1\phi_1(r) + c_2\phi_2(r)$$

$$\langle E \rangle = \frac{\langle f(r) | \hat{H} | f(r) \rangle}{\langle f(r) | f(r) \rangle}$$

Substitute and solve $\partial\langle E \rangle / \partial c_1 = \partial\langle E \rangle / \partial c_2 = 0$. Each gives a linear *secular equation* in c_1 and c_2 :

$$\begin{pmatrix} H_{11} - E & H_{12} - S_{12}E \\ H_{12} - S_{12}E & H_{22} \end{pmatrix} \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} = 0$$

where $H_{ij} = \langle \phi_i | \hat{H} | \phi_j \rangle$ is a *matrix element* and $S_{ij} = \langle \phi_i | \phi_j \rangle$ is an *overlap*. If $S_{ij} = 0$, basis is *orthogonal*, problem simplifies. If $S_{ij} \approx 1$, basis is *redundant*, not efficient!

Evaluate *secular determinant*

$$\begin{vmatrix} H_{11} - E & H_{12} - S_{12}E \\ H_{12} - S_{12}E & H_{22} \end{vmatrix} = 0$$

Gives a quadratic in E . Yields two solutions, which would be approximations to the *1s* and *2s* orbital energies of hydrogen. Back substitution to get coefficients:

$$\begin{array}{ll} 1s: \langle E_{1s} \rangle > E_{1s,\text{true}} & c_1^{1s} \text{ and } c_2^{1s} \\ 2s: \langle E_{2s} \rangle > E_{2s,\text{true}} & c_1^{2s} \text{ and } c_2^{2s} \end{array}$$

Note we always get one solution for each basis function. Secular matrix grows as the square of the number of basis functions, gets expensive to find roots.

If basis is not orthogonal, common to *orthogonalize*. Find linear transformation that makes $\langle S_{ij} = \delta_{ij}$. Evaluate

$$\mathbf{c}' = \mathbf{S}^{1/2} \mathbf{c} \rightarrow \hat{\mathbf{H}}' = \mathbf{S}^{-1/2} \mathbf{H} \mathbf{S}^{1/2}$$

$$\begin{pmatrix} H'_{11} - E & H'_{12} \\ H'_{12} & H'_{22} \end{pmatrix} \begin{pmatrix} c'_1 \\ c'_2 \end{pmatrix} = 0$$

$$\mathbf{H}'\mathbf{c}' = E\mathbf{c}'$$

Secular equations reduce to standard linear eigenvalue problem. All the tricks of linear algebra can be applied to find the *eigenvalues* (orbital energies) and *eigenvectors* (wavefunctions). Called *diagonalizing* the matrix. Tricks can be used to find the lowest energy roots only.

Same basic idea is used in virtually all calculations on atoms, molecules, Basis of *semi-empirical* and *first principles* methods.

3.6 Spin

Can't leave the H atom without mentioning electron *spin*. Non-relativistic QM gives us three quantum numbers. Relativity teaches that space and time are equivalent. Relativistic H atom solutions introduce a 4th degree of freedom that, under many circumstances, decouples from other three. Call it the electron *spin*, because it behaves like the electron has an intrinsic quantum angular momentum with magnitude $s = 1/2$.

$$\begin{aligned} m_s &= +1/2, \quad \text{"spin up"}, \quad \alpha \\ m_s &= -1/2, \quad \text{"spin down"}, \quad \beta \end{aligned}$$

m_s specifies z component of angular momentum, $s_z = m_s \hbar$.

To fully specify state of H atom, must specify all four quantum numbers.

4 (Two is too) many electrons

Helium: next (after hydrogen) simplest atom

In a sense, we “know” the answer... $1s^2$. But is this same $1s$ as H? No! Different nuclear charge, interactions between the two electrons. This is an approximation and a very convenient shorthand!

4.0.1 Schrödinger equation for He

Wavefunction $\Psi(\mathbf{r}_1, \mathbf{r}_2)$, atom energy E .

Define 1-electron operator for each electron, in atomic units. Include kinetic energy of electron and its attraction to nucleus of charge $Z = 2$:

$$\hat{h}_i = -\frac{1}{2}\nabla_i^2 - \frac{Z}{|\mathbf{r}_i|}$$

Looks similar to hydrogen atom.

BUT, electrons also repel. Total Schrödinger equation for He:

$$\left\{ \hat{h}_1 + \hat{h}_2 + \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} \right\} \Psi(\mathbf{r}_1, \mathbf{r}_2) = E\Psi(\mathbf{r}_1, \mathbf{r}_2)$$

Last term accounts for electron-electron electrostatic repulsion. Makes problem non-separable and really hard to solve. (How many solutions are there?)

Generalize to n -electron atom, in atomic units:

$$\hat{H} = \sum_i \hat{h}_i + \sum_{j>i+1} \frac{1}{|\mathbf{r}_j - \mathbf{r}_i|} \quad (24)$$

$$\hat{H}\Psi(\mathbf{r}_1, \dots, \mathbf{r}_n) = E\Psi(\mathbf{r}_1, \dots, \mathbf{r}_n) \quad (25)$$

First summation over all electrons, second gets all electron pairs.

Solutions are many-dimensional functions of the coordinates of all the electrons. Cannot solve this analytically, although approaches exist (eg quantum Monte Carlo) that can in principle get very close. Thankfully, though, we can make approximations that work out really well. We'll look at three historically important ones.

4.1 The Hartree atom

Simplest approach is to approximate Ψ . Douglas Hartree (1897-1958) writes:

$$\Psi(\mathbf{r}_1, \mathbf{r}_2) \approx \psi_1(\mathbf{r}_1) \cdot \psi_2(\mathbf{r}_2)$$

So-called Hartree product. Can't be right. It gives the probability of two electrons being in the same place as some number > 0 ! Neglects *electron correlation*. How to apply?

1. Apply variational principle: What's the best possible set of ψ_i ? We'll say best are the set that give the lowest expectation value of energy.

$$\langle E \rangle = \langle \Psi | \hat{H} | \Psi \rangle / \langle \Psi | \Psi \rangle \quad (26)$$

$$\frac{\delta \langle E \rangle}{\delta \psi_i} = 0, \forall i \quad (27)$$

2. Lagrange multipliers to impose orthonormality constraint on ψ_i :

$$\langle \psi_i | \psi_j \rangle = \delta_{ij} \quad (28)$$

$$L = \langle E \rangle - \sum_{i,j} \epsilon_{ij} (\langle \psi_i | \psi_j \rangle - \delta_{ij}) \quad (29)$$

$$\delta L = 0 \quad (30)$$

3. Coupled, one-electron Hartree eigenvalue equations for energy-optimal ψ_i :

$$\{\hat{h}_i + \hat{v}_i^{\text{Hartree}}\} \psi_i(\mathbf{r}_1) = \epsilon_i \psi_i(\mathbf{r}_1) \quad (31)$$

$$\hat{v}_i^{\text{Hartree}}(\mathbf{r}_i) = \sum_{j \neq i} \int |\psi_j(\mathbf{r}_2)|^2 \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (32)$$

Have to solve this for all n electrons of an atom/molecule. “Hartree potential” represents Coulomb repulsion between electron i and all other electrons, *averaged* over position of those electrons. Always positive. This is a *mean field* approximation. Note appearance of “one electron” energies, ϵ_i , kinetic energy plus repulsion of electron with all others. Total energy is sum of these ϵ_i corrected to avoid overcounting repulsions:

$$\langle E \rangle = \sum_i \epsilon_i - \frac{1}{2} \sum_i \langle \psi_i | \hat{v}_i^{\text{Hartree}} | \psi_i \rangle$$

Presents an obvious difficulty. If we don’t know ψ_j ahead of time, how can we even construct Hartree equations, let alone solve them? Hartree offered a numerical solution, in the 1930’s, called the **self-consistent field (SCF) approach**:

1. Guess an initial set of ψ_i , one for each electron (he did this on a grid, and jumping ahead a bit, allowed each ψ_i to represent two electrons)
2. Construct Hartree potential for each ψ_i
3. Solve the n differential equations for n new ψ_i
4. Compare new to old ψ_i
5. If the same within a desired tolerance, you are done!
6. If not, return to step 2, using new ψ_i , and repeat.

Hartree’s father did this by hand for all the atoms of the periodic table, tabulating wavefunctions and energies for all the electrons in each. See Hartree, Douglas R. *The Calculation of Atomic Structures* (1957). For instance, for He, he’d solve one equation, self-consistently, to get one ψ_1 , and then combine to get $\Psi(1,2) = \psi_1(1)\alpha(1)\psi_1(2)\beta_2$. Tedious! Qualitatively great, quantitatively not so hot. Mean-field approximation just not so hot.

Nonetheless, basic idea of representing many-body wavefunction in terms of “orbitals,” of setting up orbital equations, and solving using a self-consistent procedure, remain today at the heart of virtually all electronic structure calculations. Hurrah Hartree!

Note: It would be very cool to write a simple Python code to illustrate the SCF procedure for two electrons in an atom. Could be done on a grid or in a basis. See eg <http://www.users.csbsju.edu/~frioux/scf/scf-he.pdf>.

4.2 The Pauli principle

One big conceptual short-coming of the Hartree model is that it treats the electrons as if they were distinguishable. QM says electrons are indistinguishable. Furthermore, they have a quantized angular momentum, called a spin, that is either up or down, making them fermions.

Pauli principle: The wavefunction of a multi-particle fermion system must be anti-symmetric to coordinate exchange.

$$\Psi(\mathbf{x}_1, \mathbf{x}_2) = -\Psi(\mathbf{x}_2, \mathbf{x}_1)$$

Here the coordinate \mathbf{x} includes both the position and the spin (up or down, α or β) of the electron.

Sorry Hartree. Can fix for He by writing

$$\Psi(\mathbf{x}_1, \mathbf{x}_2) = \psi_1(\mathbf{r}_1)\psi_1(\mathbf{r}_2) (\alpha(1)\beta(2) - \beta(1)\alpha(2))$$

Hey, gentle reader, check, does this work? Yes! Exchanging the coordinates changes the sign but keeps everything else the same. Normalizing is easy if we take ψ_1 to be normalized and recall that spin functions are orthogonal:

$$\Psi(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{2}}\psi_1(\mathbf{r}_1)\psi_1(\mathbf{r}_2) (\alpha(1)\beta(2) - \beta(1)\alpha(2))$$

Note it is impossible to construct an antisymmetric wavefunction in which both electrons have the same spatial function *and* the same spin. Two electrons cannot have the same space and spin variables.

4.3 Slater determinants and Hartree-Fock

Slater determinant a general way to assure that a wavefunction satisfies Pauli principle:

$$\Psi = \frac{1}{\sqrt{n!}} \begin{vmatrix} \psi_1(1) & \psi_2(1) & \cdots & \psi_n(1) \\ \psi_1(2) & \psi_2(2) & \cdots & \psi_n(2) \\ \vdots & \vdots & \ddots & \vdots \\ \psi_1(n) & \psi_2(n) & \cdots & \psi_n(n) \end{vmatrix} = |\psi_1\psi_2\cdots\psi_n\rangle$$

Swapping rows swaps coordinates and, by rules of determinants, changes sign.

Let's compare. Two spin-paired electrons in two different orbitals:

$$\begin{vmatrix} \psi_1(1)\alpha(1) & \psi_2(1)\beta(1) \\ \psi_1(2)\alpha(2) & \psi_2(2)\beta(2) \end{vmatrix} = \psi_1(1)\psi_2(2)\alpha(1)\beta(2) - \psi_2(1)\psi_1(2)\beta(1)\alpha(2)$$

Antisymmetric? What happens when the two electrons have the same spatial coordinate?

Two spin-aligned electrons in two different orbitals:

$$\begin{vmatrix} \psi_1(1)\alpha(1) & \psi_2(1)\alpha(1) \\ \psi_1(2)\alpha(2) & \psi_2(2)\alpha(2) \end{vmatrix} = (\psi_1(1)\psi_2(2) - \psi_2(1)\psi_1(2))\alpha(1)\alpha(2)$$

What happens now?

Exchange guarantees that two electrons of same spin cannot be in the same place! No such guarantee for electrons of opposite spin.

4.4 Hartree-Fock equation

Same song and dance:

1. Apply variational principle to Slater determinant. The best ψ_i are those that minimize the expectation value of the energy.
2. Use method of Lagrange multipliers to keep ψ_i orthogonal.

For simplicity, restrict ourself to cases with an even number of electrons N , all spin-paired, so two electrons in every orbital. Let index j run over all occupied orbitals. Arrive at **restricted Hartree-Fock** equations:

$$\{\hat{h}_i + \hat{v}_i^{\text{Hartree}} + \hat{v}^{\text{exchange}}\}\psi_i(\mathbf{r}_1) = \epsilon_i\psi_i(\mathbf{r}_1) \quad (33)$$

$$\hat{v}_i^{\text{Hartree}}(\mathbf{r}_1) = 2 \sum_{j \neq i} \int |\psi_j(\mathbf{r}_2)|^2 \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (34)$$

$$\hat{v}_i^{\text{exchange}}(\mathbf{r}_1)\psi_i(\mathbf{r}_1) = -\psi_j(\mathbf{r}_1) \sum_{j \neq i} \int \psi_j(\mathbf{r}_2) \cdot \psi_i(\mathbf{r}_2) \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (35)$$

Yikes! Slater determinant wavefunction results in appearance of the “exchange” operator, which turns a ψ_i into a ψ_j . Exchange operator is not a simple multiplication. Must be solved self-consistently, and is much harder to do than the simple Hartree expression.

Slight simplification possible, noting that $i = j$ terms cancel out and slightly redefining operators:

$$\{\hat{h}_i + \hat{v}_i^{\text{Hartree}} + \hat{v}^{\text{exchange}}\}\psi_i(\mathbf{r}_1) = \epsilon_i\psi_i(\mathbf{r}_1) \quad (36)$$

$$\hat{v}^{\text{Hartree}}(\mathbf{r}_1) = 2 \sum_j \int |\psi_j(\mathbf{r}_2)|^2 \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (37)$$

$$\hat{v}_i^{\text{exchange}}(\mathbf{r}_1)\psi_i(\mathbf{r}_1) = -\psi_j(\mathbf{r}_1) \sum_j \int \psi_j(\mathbf{r}_2) \cdot \psi_i(\mathbf{r}_2) \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (38)$$

Now “Hartree potential” is the same for all orbitals/electrons. We can define the “charge density” to be

$$\rho(\mathbf{r}) = 2 \sum_j |\psi_j(\mathbf{r})|^2$$

(units of charge/unit volume, multiply by e to get a charge). The Hartree potential can be written

$$\hat{v}^{\text{Hartree}}(\mathbf{r}_1) = \int \frac{\rho(\mathbf{r}_2)}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2$$

This is the Coulomb repulsion of an electron with all electrons, *including itself*! Called Poisson equation, well known in classical physics. Because it involves a Coulomb repulsion, will see either \hat{v}^{Hartree} or \hat{v}^{Coulomb} . I'll often write $\hat{v}^{\text{Coulomb}}[\rho(\mathbf{r})]$, to emphasize that the Coulomb potential is a *functional* of the charge density.

(Just to make sure we are following units around, the Coulomb potential has units of energy/charge, eg in SI it would be J/C and would have $e/4\pi\epsilon_0$ in front.)

The “exchange potential” cancels out the “self-interaction” of an electron with itself, and insures that two electrons of the same spin cannot be in the same place, ie, the wavefunction vanishes whenever the spatial coordinates of two electrons are the same. It cannot be written simply in terms of the charge density.

4.4.1 Basis of wavefunction theory (WFT)

Hartree-Fock model is much better than Hartree alone, widely implemented in codes. Not particularly good by today's standards. However, it is systematic and rigorous, by requiring exact adherence to the Pauli principle, and it can be systematically improved. It is the foundational basis of all wavefunction theory (WFT) models, all of which are characterized by exactly treating exchange. The only approach some people call *ab initio*.

4.5 Hartree-Fock-Slater

In 1951 John Slater introduced an approximation to the Hartree-Fock model that turned out to anticipate a whole new approach to solving the electronic structure problem, called *density functional theory*.

Rewrite exchange part as (and shorten “exchange” to “x”):

$$\hat{v}_i^x(\mathbf{r}_1)\psi_i(\mathbf{r}_1) = -\psi_j(\mathbf{r}_1) \sum_j \int \psi_j(\mathbf{r}_2) \cdot \psi_i(\mathbf{r}_2) \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \quad (39)$$

$$= -\psi_j(\mathbf{r}_1) \sum_j \int \psi_j(\mathbf{r}_2) \cdot \psi_i(\mathbf{r}_2) \frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \cdot \frac{\psi_i(\mathbf{r}_1)\psi_i(\mathbf{r}_1)}{\psi_i(\mathbf{r}_1)\psi_i(\mathbf{r}_1)} \quad (40)$$

$$= - \left[\int \frac{\rho_i^x(\mathbf{r}_1; \mathbf{r}_2)}{|\mathbf{r}_2 - \mathbf{r}_1|} d\mathbf{r}_2 \right] \psi_i(\mathbf{r}_1) \quad (41)$$

$$\rho_i^x(\mathbf{r}_1; \mathbf{r}_2) = \sum_j \frac{\psi_i(\mathbf{r}_1)\psi_j(\mathbf{r}_2)\psi_j(\mathbf{r}_1)\psi_i(\mathbf{r}_2)}{\psi_i(\mathbf{r}_1)\psi_i(\mathbf{r}_2)} \quad (42)$$

This looks like the Coulomb expression, but the density thing is different for each orbital i . The “exchange density” does have units of charge density enters in the same way, but with minus sign, to the electron density. Suggests that exchange can be thought of as an electron “hole” around an electron. This exchange density has some special properties:

1. Every electron at any position \mathbf{r}_1 has an exchange hole around it equal to one electron of the same spin as itself:

$$\int \rho_i^x(\mathbf{r}_1; \mathbf{r}_2) d\mathbf{r}_2 = 1$$

2. The exchange hole exactly cancels out all electrons of the same spin at the electron location. Ie, it exactly fixes self-interaction:

$$\rho_i^x(\mathbf{r}_1; \mathbf{r}_1) = \sum_j |\psi_j(\mathbf{r})|^2$$

Thus, the Coulomb repulsion felt by an electron is diminished by an exchange hole that follows the electron around, exactly canceling out the charge at its current location. It's not necessarily spherical and is not the same for all orbitals, but the fact that it has these general properties gives hope that it can be approximated somehow.

Hey, I have an idea! (Actually, Slater had an idea.) What if we had a homogeneous (density the same everywhere) gas of electrons, like electrons of a given density ρ in an infinite box? By symmetry the exchange hole would be spherical, and if it must integrate to 1, then it must have a radius (factor of 2 comes from fact we are only including electrons of the *same* spin):

$$R_{\text{hole}} = \left[\frac{4\pi\rho/2}{3} \right]^{1/3}$$

The potential felt by an electron due to this spherical hole is

$$\hat{v}^x = -\frac{1}{2} \int_{\text{sphere}} \frac{\rho}{r} dr = -\left[\frac{9\pi\rho}{4} \right]^{1/3}$$

Now, let's assume that an electron in a real system experiences an exchange hole potential at any point exactly like that of a homogeneous electron gas of the same density at that point. This is the basis of the *Hartree-Fock-Slater* model:

$$\hat{v}^{x,HFS}(\mathbf{r}_1) = -\frac{3}{2} \left[\frac{3\rho(\mathbf{r}_1)}{\pi} \right] - C\rho(\mathbf{r}_1)^{1/3}$$

Some ambiguity as to the right value of the constant C , so sometimes just taken as a parameter.

Can now write the *Hartree-Fock-Slater* equation:

$$\left\{ \hat{h} + \hat{v}^{\text{Coulomb}}[\rho] + \hat{v}^{x,HFS}[\rho] \right\} \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r})$$

This is **much** simpler to solve than Hartree-Fock equation, because the left hand side is the same for all electrons given a total density $\rho(\mathbf{r})$. Still must be solved iteratively, using the *self-consistent field*.

4.5.1 Notes

1. Exchange potential scales with the total number of electrons around: more electrons (like near a nucleus) means a more compact, denser exchange hole, more electron exchange "screening," a greater decrease in potential energy. Further from nucleus, more diffuse exchange hole, less screening.
2. Screening is not exact, though; does not exactly cancel self-interaction. Clearest in one-electron case: Coulomb and exchange potentials should then exactly cancel, which they evidently do not! HFS energy of an H atom is not exactly 0.5 au!

3. From a computational point of view, the exchange potential goes from being the hard thing to evaluate to being the easy thing. The Coulomb potential takes more effort to evaluate, and tricks are often implemented to simplify that, like fitting the density to an auxiliary basis set. On the other hand, the $1/3$ power makes the exchange potential non-analytic, and solution of the HFS equation (and all DFT methods) involves some form of numerical quadrature.
4. How does the HFS model do? Pretty darn well, in particular for calculating the structures of things, and it works nicely for things like metals. Not a bad deal! Way to go, Slater!
5. Another aside: back in the day, the numerical implementations of $X\alpha$ were very crude and sometimes gave unreasonable results (like linear water!). Slater still sold it very hard, which did not enamor him or all of DFT to the chemical community, although the physics community was far more accepting. For many years DFT was unaccepted by chemists, until solid numerical implementations in codes like **Gaussian** brought it to the mainstream.

4.5.2 Basis of density functional theory (DFT)

Slater's arguments are not rigorous. However, as we will see later, they can be made rigorous. HFS is the very simplest example of a *density functional theory* model, because it is a model built entirely on charge density. Such approach is justifiable.

4.6 Implementations

4.6.1 GAMESS

Hartree-Fock method *always* paired with *basis set* methods and implemented in the codes available at <http://webmo.net>. Example GAMESS input for Hartree-Fock Ar:

```
$CONTRL SCFTYP=RHF RUNTYP=ENERGY ISPHER=1
      ICHARG=0 MULT=1 COORD=CART $END
$BASIS GBASIS=CCT $END
$DATA
Ar
OH 1

Ar 18 0.00000000 0.00000000 0.00000000
$END
```

And for Hartree-Fock-Slater Ar:

```
$CONTRL SCFTYP= RHF RUNTYP=ENERGY DFTTYP=Slater ISPHER=1
      ICHARG=0 MULT=1 COORD=CART $END
$BASIS GBASIS=CCT $END
$DATA
Ar
OH 1

Ar 18 0.00000000 0.00000000 0.00000000
$END
```

4.6.2 FDA

Hartree-Fock-Slater is intrinsically numerical. Historically interesting is the Herman-Skillman code, that solves the problem numerically on a grid. Available to us as the `fda` code, see <https://www.chemsoft.ch/qc/fda.htm> and [./Resources/OOREAD.ME](#).

Ar input:

```
300 0.0001 30.0
50 0.00001 0.10 0.50 0.682 0.0042
18.0 5
1 0 1.0 1.0
2 0 1.0 1.0
2 1 3.0 3.0
3 0 1.0 1.0
3 1 3.0 3.0
```

Output at [./Resources/Ar.out](#).

4.7 Performance

One metric is the ability to predict ionization energies.

Koopman's theorem: The negative of the energy of an occupied orbital ($-\epsilon_i$) approximates the energy to extract an electron from that orbital, i.e. to ionize the system. The energy of a virtual orbital approximates the energy to add an additional electron to a system, i.e. the electron affinity. Assumes no relaxation of orbitals.

Figure 7: HFS vs exact ionization energies

4.8 Correlation

If solved to reasonable precision, both the Hartree-Fock and Hartree-Fock-Slater models work pretty darn well for things like the shapes of molecules, structures of solids, charge distributions, vibrational frequencies, Don't work so well for computing things that involve making and breaking bonds, like a reaction energy or an activation energy.

Why? All the models discussed here neglect *electron correlation*, the fact that the potential felt by an electron *is* a function of the instantaneous positions of all the other electrons. The contribution of correlation to absolute energies is not big by proportion, but it is very important to energy differences. Any "orbital" model cannot capture correlation. It can be introduced systematically and exactly into H-F models (at great computational expense) and systematically and approximately into DFT models (at much more modest expense). Hence the popularity of DFT!

5 Practical electronic structure

5.1 Born-Oppenheimer approximation

In principle all nuclei and electrons should be described quantum mechanically. For H_2 , for instance, true wavefunction would be a function of the positions of nuclei and electrons, $\Upsilon(\mathbf{r}_1, \mathbf{r}_2, \mathbf{R}_\alpha, \mathbf{R}_\beta)$.

Nuclei much heavier than electrons and move much more slowly. Assume nuclei are fixed in space (“clamped”) and electrons move in static field of those electrons. Equivalent to assuming that nuclear kinetic energy is decoupled from electron dynamics. Only change is that

$$\hat{h} = -\frac{1}{2}\nabla^2 - \sum_{\alpha} \frac{Z_{\alpha}}{|\mathbf{r} - \mathbf{R}_{\alpha}|}$$

Schrödinger equation becomes parametric in nuclear positions; solutions $E(\mathbf{R}_\alpha, \mathbf{R}_\beta)$ define a potential energy surface (PES).

$$E_{\text{PES}}(\mathbf{R}_\alpha, \mathbf{R}_\beta) = E_{\text{Schr}} + \frac{1}{2} \sum_{\alpha, \beta} \frac{Z_{\alpha} Z_{\beta}}{|\mathbf{R}_{\beta} - \mathbf{R}_{\alpha}|}$$

5.2 Model chemistry

Essentially always start with

$$\left\{ \hat{h} + v_{\text{Coulomb}}[\rho] + v_{\text{exchange}}[\psi_i] + v_{\text{correlation}}[\psi_i] \right\} \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}) \quad (43)$$

Standard models of today all treat the one-electron and Coulomb pieces exactly and treat the electron-electron interactions at various levels of approximation.

	v_{exchange}	$v_{\text{correlation}}$	
Wave function theory (WFT)			
Hartree	self-interaction	neglect	historic
Hartree-Fock	exact	neglect	superceded
MPn, CC	exact	perturbative	state-of-the-art
CI	exact	variational	specialized
Density functional theory (DFT)			
Hartree-Fock-Slater	$[\rho^{4/3}]$	neglect	historic
Local density approximation (LDA)	$[\rho^{4/3}]$	$[\rho]$	general purpose solids
Generalized gradient approximation (GGA)	$[\rho, \nabla \rho]$	$[\rho, \nabla \rho]$	general purpose solids/surfaces
“Improved” GGA (RPBE, BEEF, Mxx)	$[\rho, \nabla \rho]$	$[\rho, \nabla \rho]$	general purpose
Hybrid (B3LYP, PBE0, HSE06)	$\approx \text{exact}$	$[\rho, \nabla \rho]$	general purpose molecules specialty solids/surfaces
Meta GGA	$[\rho, \nabla \rho, \nabla^2 \rho]$	$[\rho, \nabla \rho, \nabla^2 \rho]$	developing

The choice of the electronic structure model is the most fundamental approximation in applying these methods. Determined from experience and need.

Specification in GAMESS (<https://www.msg.chem.iastate.edu/GAMESS/GAMESS.html>) is a bit arcane. Default is Hartree-Fock. To specify DFT model, use

```
$CONTRL DFTTYP = Slater (HFS), SVWN (LDA), PBE (GGA), B3LYP (Hybrid), M06 (Minnesota optimi
```

5.2.1 Beyond Hartree-Fock

Many methods available. See manual for full description. Most common is second-order perturbation theory, “MP2”:

```
$CONTRL MPEVL=2 $END
```

If you want a very high quality number, have a big computer and time to wait, try “coupled cluster”:

```
$CONTRL CCTYP=CCSD(T) $END
```

5.3 Bring back the basis sets

The one-electron equations eq 5.2 give us defining expressions for the energy-optimal orbitals, but they aren’t convenient to solve for anything more complicated than an atom. Expand solutions in a basis set:

$$\psi_i(\mathbf{r}) = \sum_{\nu} C_{\mu i} \phi_{\nu}(\mathbf{r})$$

Often atom-centered. You’ll see the term “linear combination of atomic orbitals,” LCAO.

Abbreviate $\hat{f}\psi_i = \epsilon_i\psi_i$. Substitute in ψ_i , multiple through by a basis function ϕ_μ :

$$\sum_{\nu} F_{\mu\nu} C_{\nu i} = \epsilon_i \sum_{\nu} S_{\mu\nu} C_{\nu i}, \quad \mathbf{FC} = \mathbf{SC}\epsilon$$

where

$$F_{\mu\nu} = \langle \psi_\mu | \hat{f} | \phi_\nu \rangle \quad S_{\mu\nu} = \langle \psi_\mu | \phi_\nu \rangle$$

Matrix equation to solve.

Historically interesting, “semi-empirical” methods (MNDO, ...) worked by parameterizing the matrix elements against atom properties.

Recall \hat{f} depends on the density, which can be written

$$\rho(\mathbf{r}) = \sum_{\mu\nu} P_{\mu\nu} \phi_\mu(\mathbf{r}) \phi_\nu(\mathbf{r}), \quad P_{\mu\nu} = 2 \sum_i C_{\mu i} C_{\nu i}$$

Depending on implementation, pieces of \hat{f} can often be computed just once and reused, eg one-electron integrals $\langle \phi_\mu | \hat{h} | \phi_\nu \rangle$.

Algorithm:

1. Put your atoms somewhere in space
2. Select a basis
3. Pre-compute what you can
4. Guess some coefficients/density/density matrix
5. Construct secular matrix elements
6. Solve secular matrix equation for C and ϵ
7. Construct and compare new density to old
8. Update density and repeat, or ...
9. ... if less than tolerance, all done!

ALWAYS check to be sure result has converged, to the state you want!

5.4 H2O Energy Example

Hartree-Fock calculation on H₂O, minimal (STO-3G) basis set.

```

Results get labeled by symmetry labels.

See [./Resources/H2O-C2V.gamout](#).

5.6 Examples

5.6.1 Dissociating H₂⁺ example

Compute energy vs distance. Should dissociate to H atom and H⁺ ion.

Oops, come on, LDA! Illustrates self-interaction problem in LDA. Electron is too eager to be diffuse, spreads out over both atoms when it should localize on one.

5.6.2 Dissociating HHe⁺ example

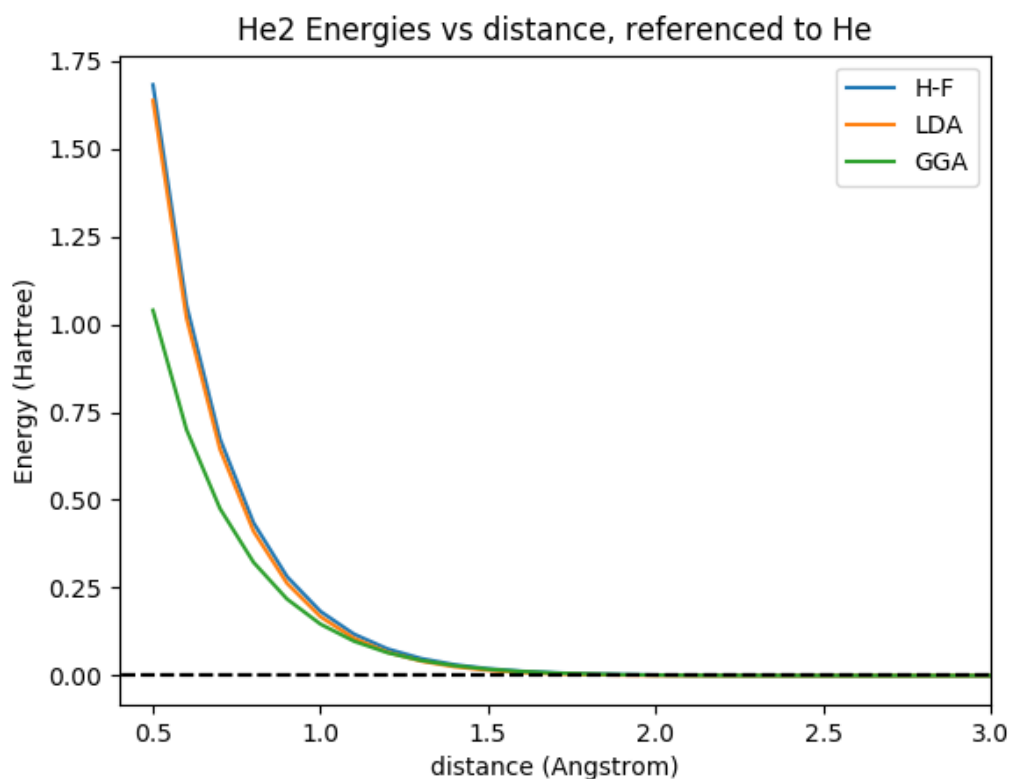

Compare Hartree-Fock and LDA for H–He⁺ vs distance. (Isoelectronic to H₂, but avoids any problems with symmetry. Should dissociate to H⁺ and He. Does it?

```
$BASIS GBASIS=STO NGAUSS=3 $END
$CONTRL SCFTYP=RHF RUNTYP=ENERGY ICHARG=1 MULT=1 $END
$DATA
Title
C1
H      1.0      0.    0.    0.
He     2.0      0.    0.   XXX
$END
```

Equilibrium distance? How's the dissociation state? Bond energy? Truth is about -0.075 Hartree. LDA has advantage of cancellation of errors between exchange and correlation errors. A good thing!

5.6.3 Dissociated He2 example

5.7 Open-shell systems

First, some jargon related to unpaired electrons:

# unpaired electrons	S	$2S + 1$	name
0	0	1	singlet
1	1/2	2	doublet
2	1	3	triplet
3	3/2	4	quartet

Model has to be generalized somewhat to deal with systems with unpaired electrons. One approach is to construct wavefunctions that are exactly spin-adapted (eigenfunctions of the \hat{S} operator). Possible in the Hartree-Fock world, but messy. More common is to relax that constraint a bit, define different orbital wavefunctions for spin-up and spin-down electrons, called *unrestricted* or *spin-polarized* (opposite of *non-spin-polarized*!). Means that electron density has different spin-up and spin-down parts.

Controlled in GAMESS using the \$CONTRL group:

```
$CONTRL SCFTYP = RHF    non-spin-polarized, default
          SCFTYP = UHF    spin-polarized
          MULT   = 1 (default), 2,...  spin multiplicity = 1 + number of unpaired electrons
          ICHARG = 0 (default), 1,...  net charge
$END
```

5.8 Gaussian basis sets

Gaussian functions ($e^{-\zeta|\mathbf{r}|^2}$) are the most popular choice for atom-centered basis sets. They do not efficiently represent molecular wavefunctions, but one- and two-electron integrals in WFT can be solved analytically over Gaussians.

Other choices, like Slater functions ($e^{-\zeta|\mathbf{r}|}$) are possible but require numerical quadrature.

Gaussian basis sets have to be created for any given atom and must be used consistently within a set of calculations.

- Primitive is a single Gaussian function, possibly multiplied by a polynomial to look like s , p , Defined by an exponent ζ that determines how extensive (small ζ) or compact the function is.
- Contraction is a pre-set linear combination of several primitive Gaussians.
- Basis set is a predefined set of exponents and contraction coefficients appropriate for some specific atom.

5.8.1 Gaussian basis set nomenclature

- Minimal basis contains one contracted function for every atomic orbital. STO-3G is the poster child.
- Double zeta contains two contracted functions for every atomic orbital
- Split valence is more common, single zeta in core, double zeta in valence, typical of Pople basis sets, eg "6-31G"
- Triple-split valence would be "6-311G"

- Spherical vs Cartesian determines whether a d function have 6 or 5 parts (the sixth of which is an s).
- Polarization functions are functions of one angular momentum greater than the highest angular momentum occupied states, eg p function for H, or d function for C. Important to capture the polarization of charge when atoms make molecules. Arcane nomenclature, eg 6-31G(d,p) or 6-31G**.
- Diffuse functions are small exponent functions to describe anions or loosely bound electrons. Again arcane nomenclature, eg 6-31+G(d,p). Yech.
- Correlation consistent and atomic natural orbital are series of basis sets that are constructed to be efficient and to improve systematically.
- Complete basis set (CBS) limit is notion of extrapolating energies from a series of systematically improving basis sets. Very common in high accuracy calculations.

5.8.2 Standard basis sets in GAMESS

Specified in \$BASIS group. Some common choices, in increasing level of sophistication:

Name	Type	Flags
	Pople type	The most venerable and widely used
STO-3G	Minimal	GBASIS=STO NGAUSS = 3
3-21G	Split valence	GBASIS=N21 NGAUSS=3
6-31G(d)	Split valence polarized	GBASIS=N31 NGAUSS =6 NDFUNC=1
6-311+G(d,p)	Triple-split valence polarized and augmented	GBASIS=N311 NGAUSS=6 NDFUNC=1 NPFUNC=1 DIFFSP=1
	Polarization-consistent	Good for DFT
PC0	Split valence	GBASIS=PCseg-0 ISPHER=1
PC1	Split valence polarized	GBASIS=PCseg-1 ISPHER=1
PC2	Triple split double polarized	GBASIS=PCseg-22 ISPHER=1
	Correlation-consistent	Good for MP2 and beyond
cc-pVDZ	Split valence polarized	GBASIS=CC2
cc-pVTZ	Triple split double polarized	GBASIS=CC3
aug-cc-pvDZ	augmented with diffuse functions	GBASIS=ACC2
	Effective core potentials	Good for treating heavy atoms
SBKJC	Split valence + core potential	GBASIS=SBKJC
Hay-Wadt	Split valence + core potential	GBASIS=HW

Complicated field, which is why the old standards live on in routine calculations. Optimal approach is to employ a composite model, calibrated by someone else, with well defined set of basis functions and treatments of exchange and correlation. A composite model pieces together results from a number of different calculations to estimate a higher accuracy model.

5.9 Electron cores

Low energy “core” electrons typically don’t participate in chemical bonding but can add substantially to computational cost. Generally seek approximations, especially for heavy elements/metals.

Heart of approach is to partition an atom into core and valence parts. Seek ways to express the influence of the core on the valence without actually having to compute the core. Essentially seek to write

$$\hat{v}^{\text{ee}} \approx \hat{v}^{\text{ee,core}} + \hat{v}^{\text{ee,val}}$$

where the core potential is some simpler, composite expression of the influence of the core on the valence. Typically take the electron cores as “frozen” in the pure atomic states, and express influence on valence through angular-momentum-dependent operators parameterized against accurate atomic calculations. Goal is to recover valence wavefunctions with less effort.

5.9.1 Relativistic effects

Relativistic kinetic energy is relativistic total energy minus the rest energy:

$$T = \sqrt{p^2 c^2 + m_0^2 c^4} - m_0 c^2$$

Taylor expanding about $p^2 = 0$ gives the first-order mass-velocity correction:

$$T \approx \frac{p^2}{2m_0} - \frac{p^4}{8m_0^3 c^2}$$

Reduces to non-relativistic result when $c \rightarrow \infty$. Electrons near core move at speeds close to c , second term becomes non-negligible and diminishes their energy. Most important for s states that penetrate closest to nucleus; they shield nucleus better and other valence states rise up in energy.

Electron spin and orbital magnetic moments also couple when $l > 0$, leads to spin-orbit coupling that splits p, d, \dots states into $j = l \pm s$ states.

Darwin correction corrects s orbitals for electron and nucleus being at the same point; comes from solution of full Dirac relativistic equation for the atom.

Relativistic effects typically incorporated implicitly, by including in model for core electrons and thus capturing their effect on the valence. Spin-orbit, if necessary, added after the fact.

5.9.2 Implementations

Non-relativistic and relativistic effective core potentials (ECPs) available for many elements. These specify the potential felt by the valence electrons due to the core in terms of radial potential functions and angular projection operators. Typically these have to be combined with basis functions designed to work with them.

Most common are Hay-Wadt (LANL) and Stevens-Basch-Krause (SBK). Other more modern ones also available, like Stuttgart.

Essential to all plane-wave codes, like **Vasp**, but implemented differently. Will touch on later in class.

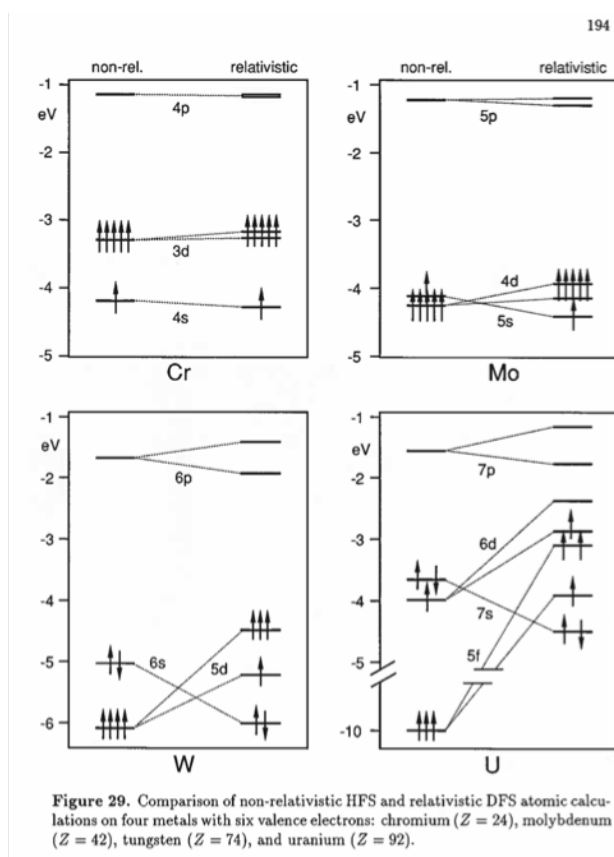

Figure 8: Comparison of Non-Relativistic and Relativistic Atomic States.

5.10 Population analysis

The molecular orbitals contain information that can be helpful in understanding structure and bonding:

- Charge density most direct representation of electron distribution

$$\rho(\mathbf{r}) = \sum_{\text{occupied}} |\psi_i(\mathbf{r})|^2 = \sum_{\mu,\nu} P_{\mu,\nu} \phi_\mu(\mathbf{r}) \phi_\nu(\mathbf{r})$$

- Moments of charge density (dipole, quadrupole), useful for thinking about molecule-molecule interactions. (Only exactly defined for neutrals!)
- Electrostatic potential, or Coulomb potential created by electrons and nuclei. More refined way of thinking about “how spots” on a molecule. Commonly used to parameterize classical forcefields, by seeking set of atom-centered charges that reproduce calculated electrostatic potential, as is done with CHELPG. Not uniquely defined.
- Population analyses, which attempt to distribute electrons to individual atoms and possibly bonds based on decomposition of molecular orbitals. Chemically it is intuitively nice to assign charge to individual atoms. There is no single “right” way to do this... the “charge” on an atom in a molecule is not uniquely defined! Consider an occupied molecular orbital ψ made up of two basis functions on two different atoms, α and β :

$$\psi = c_\alpha \phi_\alpha + c_\beta \phi_\beta \quad (44)$$

$$\langle \psi | \psi \rangle = c_\alpha^2 + c_\beta^2 + 2c_\alpha c_\beta \langle \phi_\alpha | \phi_\beta \rangle \quad (45)$$

In *Mulliken* analysis, c_α^2 is fraction of ψ assignable to the atom of α , c_β^2 fraction assigned to atom of β . Remainder is the “overlap” population, which is split evenly between the two. Summing over all occupied orbitals and subtracting nuclear charges gives *gross atomic charges*.

In *Löwdin* analysis, basis functions are pre-orthogonalized, so last term vanishes.

Both approaches very sensitive to choice of basis set. Only sensible to compare within a common model type across molecules.

- Localized orbitals is notion of creating linear combinations of ψ that satisfy some constraint for being compact. Leads to orbitals that are more naturally “bonding.”
- Natural orbitals a rigorous scheme for orthogonalizing and assigning charge. Based on recognition that there is a set of orthogonal orbitals that optimally describe the density. Localizing these give *natural bonding orbitals*. See [06Weinhold.pdf](#).
- Bader analysis another method, based on a geometric analysis of the total charge density. Define See Bader, R. F. W. *Atoms in Molecules: A Quantum Theory*; Oxford University Press: Oxford, 1990.

5.11 Molecular orbital (MO) diagrams

Correlate molecular orbitals with their parent fragments. Use to be the thing. Seldom now

5.12 Implementation details of SCF methods

Basis is often *orthonormalized* to eliminate overlap from H-F-R equation; allows equations to be solved by matrix diagonalization.

Initial density matrix **P** are obtained by solving an approximate Hamiltonian (like extended Hückel). Always beware! Initial guess can influence final converged state.

Because the number of 2-electron integrals grows as N^4 , they are sometimes calculated as needed “on-the-fly”, so-called direct SCF.

Hartree-Fock integrals can be computed analytically in a Gaussian basis. Any other choice of basis, or any DFT functional, requires integrals to be computed by quadrature. Used to be a real hang-up. Today, algorithms are very robust to establish grids and do quadrature.

5.13 SCF updating

The SCF procedure is an optimization problem: find set of coefficients that minimizes the total energy. As discussed above, success depends on a reasonable initial guess for density matrix and judicious updating. Various strategies can be used to speed and stabilize convergence, like damped mixing of previous cycles.

Second-order SCF is a convergence acceleration method that requires calculation or estimation of the first- and second-derivatives of the energy with respect to the orbital coefficients. See e.g. Chaban et al., *Theor. Chem. Accts.* **1997**, 97, 88-95.

Pulay’s “direct inversion in the iterative subspace,” or “DIIS,” is a popular and powerful acceleration procedure that extrapolates from several previous Fock matrices to predict optimal next Fock to diagonalize. **An opportunity for machine learning?**

Controlled in GAMESS using the \$SCF group.

```
$SCF DIRSCF= .T./F. controls direct scf
      SOSCF= .T./F. second-order scf
      DIIS= .F./T. direct inversion in the iterative subspace
      DAMP= .T./F. damping, on for initial iterations
$END
```

Can also control initial guess orbitals. Particularly powerful feature is to restart from converged orbitals from a previous calculations (.dat file), controlled with \$GUESS group.

```
$GUESS GUESS = HUCKEL    construct initial guess from a simple Hamiltonian
      = MOREAD    read in orbitals from $VEC group.
```

6 Potential energy surfaces

The potential energy surface (“PES”) is the sum of the repulsive energy of the nuclei and the kinetic and potential energies of all the electrons:

$$E_{\text{PES}}(\mathbf{R}_\alpha, \mathbf{R}_\beta, \dots) = E_{\text{elec}} + \sum_{\alpha=1}^N \sum_{\beta=\alpha+1}^N \frac{Z_\alpha Z_\beta e^2}{R_{\alpha\beta}} \quad (46)$$

6.1 Specifying atomic positions

6.1.1 Cartesian

Computationally straightforward but don’t correspond with our physical notion of bonds, bends, etc. Easiest to get out of a piece of software. A molecule has $3N - 6$ internal degrees of freedom ($3N - 5$ if linear), but Cartesians specify $3N$. The extra values correspond to the location of the center of mass and molecular orientation. Codes will typically center and reorient the Cartesians.

In GAMESS, would specify Cartesian coordinates for FCH2CH2F like this:

```
$CONTRL COORD=CART $END
$DATA
FCH2CH2F drag calculation
C1
C      6.0    -3.76764    0.33879    0.03727
C      6.0    -2.35246    0.34495    0.03689
F      9.0    -4.72277    0.58147   -1.18012
F      9.0    -1.59909   -0.68487   -0.83662
H      1.0    -4.04387    1.08375    0.75395
H      1.0    -3.92958   -0.71060    0.16941
H      1.0    -2.03786    0.18875    1.04760
H      1.0    -2.09983    1.28759   -0.40187
$END
```

6.1.2 Internal coordinates

These provide a more intuitive representation and can be convenient when building molecules by hand. In codes like GAMESS, most commonly defined using “z-matrix” notation. Specify each atom

in terms of its distance, angle, and dihedral angle with three previous atoms.

In Gamess, would specify z-matrix for FCH₂CH₂F like this:

```
$CONTRL SCFTYP=RHF RUNTYP=ENERGY COORD=ZMT $END
```

```
$DATA
```

```
FCH2CH2F drag calculation
```

```
C1
```

```
C
```

```
C    1    r1
```

```
F    2    r2    1    A1
```

```
H    2    r3    1    A2    3    D1
```

```
H    2    r4    1    A3    3    D2
```

```
F    1    r2    2    A1    3    D3
```

```
H    1    r3    2    A2    6    D1
```

```
H    1    r4    2    A3    6    D2
```

```
r1=1.5386
```

```
r2=1.39462
```

```
r3=1.11456
```

```
r4=1.12
```

```
A1=109.54214
```

```
A2=111.
```

```
A3=110.
```

```
D1=120.
```

```
D2=-120.5
```

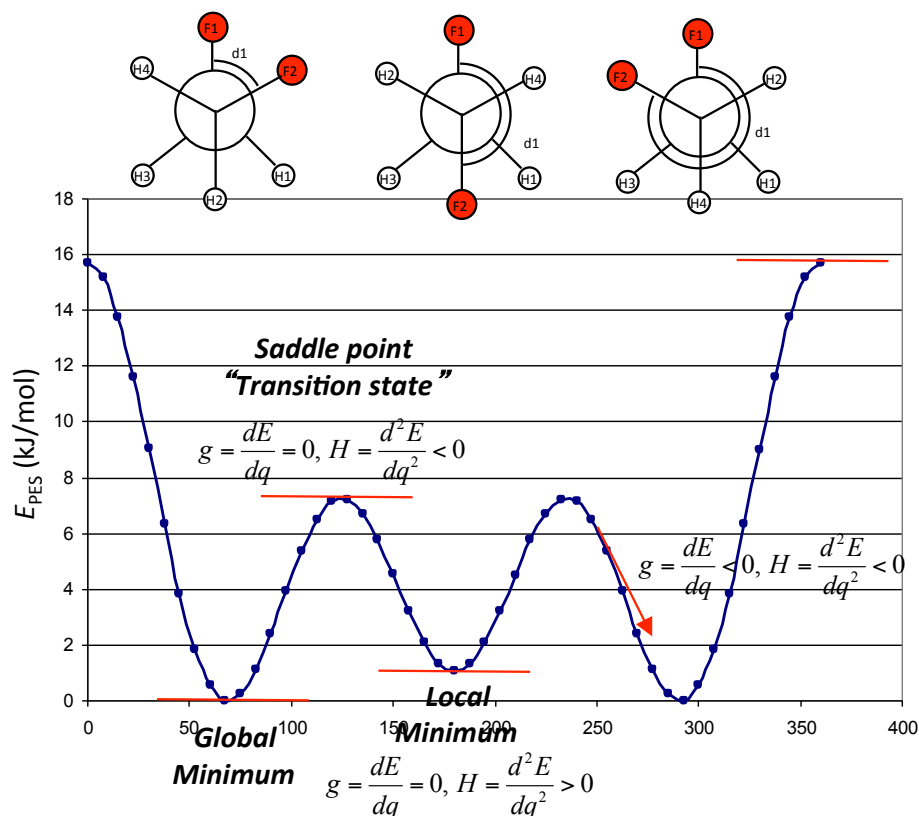

```
D3=50.
```

```
$END
```

Particularly convenient when you'd like to "scan" over the value of some coordinate. Variable can be applied to more than one independent coordinate, if the molecule has symmetry.

6.2 Features of potential energy surfaces

6.2.1 One-dimensional example

Note 3-fold periodicity as expected for rotation about a CC single bond. Note too there are some special points:

- Minima** are places where energy bottoms out. More formally, first derivative of energy, or slope, or “gradient” $g = 0$, and second derivative, or curvature, or “Hessian” $H > 0$. These are the **locally** stable conformations of the molecule. Note that lowest energy in this case is not trans, but rather gauche conformations. Are you surprised?
- Saddle points** are places where energy is maximized. Physically, corresponds to “transition states” connecting low-energy conformations. Gradient $g = 0$, but curvature $H < 0$.

6.2.2 Many-dimensional PES features

Gradient becomes vector and Hessian a matrix

$$\mathbf{g} = \begin{pmatrix} \frac{\partial E}{\partial q_1} \\ \vdots \\ \frac{\partial E}{\partial q_{3N}} \end{pmatrix} \quad \mathbf{H} = \begin{pmatrix} \frac{\partial^2 E}{\partial q_1^2} & \cdots & \frac{\partial^2 E}{\partial q_1 \partial q_{3N}} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 E}{\partial q_1 \partial q_{3N}} & \cdots & \frac{\partial^2 E}{\partial q_{3N}^2} \end{pmatrix}$$

- gradient** is vector tangent to PES. The force on an object is $\mathbf{F} = -\mathbf{g}$, so the gradients are often called the forces. Where gradient (slope) is negative, force is positive, and vice versa.

Figure 9: From Schlegel, *J. Comp. Chem.* **2003**, *24*, 1514-1527.

Force always pushes system toward nearest minimum. If the potential is harmonic, then the force constant $k = H$, so the Hessian is also called the “force constant.”

- Hessian matrix is real and symmetric. Diagonalization gives eigenvalues and eigenvectors. Eigenvectors give “natural” directions along PES (physically, the harmonic vibrational modes), and eigenvalues indicate curvature in that direction.
- Minimum on multidimensional PES has gradient vector $\mathbf{g} = 0$ and all positive Hessian eigenvalues.
- First-order saddle point, or transition state, has $\mathbf{g} = 0$ and one and only one negative Hessian eigenvalues. (Physically, one unique direction that leads downhill in energy.) Must correspond to lowest-energy point connecting two minima.
- Minimum energy pathway (MEP) or intrinsic reaction coordinate (IRC) is steepest descent pathway (in mass-weighted coordinates) from saddle point to nearby minima. Path a marble with infinite inertia would follow.
- Higher order saddle points have $\mathbf{g} = 0$ and more than one negative Hessian eigenvalue. Can always lead to lower energy first order saddle point. These generally do not have chemical significance.

In computational chemistry/materials science, it is frequently our job to identify the critical points (minima and transition states on a PES). In liquids, PES much more flat and lightly corrugated. Statistical mechanics becomes more important.

Each distinct electronic state defines its own PES. Remember that there are multiple PES's for any atom configuration, corresponding to different electronic states. Sometimes these states can interact, intersect, giving avoided crossings, conical intersections. Lead to more complicated dynamical behavior.

6.3 Energy gradients and second derivatives

6.3.1 Gradients

$$\frac{\partial E_{\text{elec}}}{\partial q_i} = \frac{\partial}{\partial q_i} \langle \Psi | \hat{H} | \Psi \rangle = \left\langle \frac{\partial \Psi}{\partial q_i} | \hat{H} | \Psi \right\rangle + \langle \Psi | \frac{\partial \hat{H}}{\partial q_i} | \Psi \rangle + \left\langle \Psi | \hat{H} | \frac{\partial \Psi}{\partial q_i} \right\rangle$$

- Hellman-Feynmann theorem says that sum of first and last terms vanish, so in principle only need to compute middle, which involves derivative of Coulomb potential and can be evaluated.
- Pulay forces are forces from first and last terms that appear when basis functions are centered on atoms. An advantage of plane-wave basis sets, for which these terms vanish.

6.3.2 Hessian

In some electronic structure models can be computed analytically. More commonly, determined from numerical differentiation of gradients. Implementations typically assume that system is at minimum.

h must be small enough to stay in the harmonic region, but big enough to avoid numerical noise swamping the gradients.

For a molecule with N atoms, to construct complete $3N \times 3N$ Hessian, have to evaluate gradients $6N$ times for two-sided differencing. Each pair of displacements completes one row of Hessian. Obviously tends to be quite expensive.

To get better precision and accuracy, could calculate more than two displacements, and could fit to a more complicated function than a harmonic potential.

6.4 Geometry optimization algorithms

6.4.1 Energy-only

- Trudge infers gradient and locates minimum by wandering around

6.4.2 Energy + gradient

- Steepest descent, just march down hill. $\mathbf{R}' = \mathbf{R} - \lambda \mathbf{g}$. Safe, very inefficient near minimum. May do line search to adapt λ .

- Conjugate gradient is steepest descent plus orthogonalization to previous step. Safe, less very inefficient, common choice when far from minima.

6.4.3 Energy + gradient + higher order

- Quasi-Newton Raphson takes advantages of both first and second derivative information:

$$\mathbf{R}' = \mathbf{R} - \mathbf{H}^{-1}(\mathbf{R})\mathbf{g}(\mathbf{R})$$

Typically do not know Hessian and it is expensive to calculate. Make an initial guess, then update Hessian with gradient information from each geometry step. “Learning” PES as we go. Generally converges very rapidly near minima, where surface is not too anharmonic.

- Rational function optimization is similar in spirit, also constructs Hessian, but uses more sophisticated (than quadratic) guess form of PES to update positions.
- Direct inversion in the iterative subspace (DIIS) uses sizes of QNR steps as estimates of error and constructs new step from linear combination of previous that minimizes error inferred from previous steps:

$$err(\mathbf{R}) = \sum_i c_i \mathbf{H}_i^{-1} \mathbf{g}_i$$

Generally very efficient in region of minimum. Algorithm can misbehave away from minima, possibly even converging to nearby saddle points, so often started with conjugate gradient steps.

6.4.4 Machine learning

All of these based on some form of assumed model of underlying PES (Taylor expand to second order around minimum). Emerging are methods that “fingerprint” structure and construct and improve energy model with each step. Remains to be seen if a new “standard” emerges.

6.4.5 Global optimizations

Simulated annealing, genetic algorithms, ..., more on the exotic side.

6.4.6 Convergence criteria

Typically determine convergence by enforcing maximum on each individual force component

GAMESS offers a limited set of algorithms.

```
$STATPT METHOD = NR      ! Quasi-Newton Raphson
                   = RFO   ! rational function optimization
OPTTOL = 0.0001 ! convergence criterion in au/bohr.
HESS = GUESS     ! guess an initial Hessian
                   = READ  ! read from $VIB group
$END
```

6.5 Specify GAMESS calculation type

Specified in \$CONTRL group by RUNTYP flag:

Calculation	RUNTYP=
Single-point energy	Energy
Single-point energy + force	Gradient
Geometry optimization	Optimize
Linear scan over PES	Scan
Energy + second derivative	Hessian
Transition state search	Sadpoint
Intrinsic reaction coordinate	IRC

Note too that specifying EXETYP=CHECK will check your input without actually running the job.

Hessian (force) calculation can be done analytically or by numerical differentiation of forces, depending on electronic structure method:

```
$FORCE METHOD = ANALYTICAL
                = SEMINUM
      VIBSIZ = 0.01      ! step size (bohr)
$END
```

6.6 Efficient coordinate systems

Optimizations are most efficient in coordinate system that diagonalizes Hessian, so that optimizations along each direction are (nearly) independent. Large off-diagonal Hessian terms imply strong coupling. Cartesian coordinates do not reflect physical forces in system and are generally poor choice/slow convergence for optimizations. Can choose other coordinate systems. Forces/Hessian always computed in cartesians, so any other coordinate system requires transformations back and forth.

- Cartesians simplest to implement, consistent performance. Typically only choice in supercell calculations.
- Z-matrix are easy to define and use for organic molecules with no rings. For $3N - 6$ degrees of freedom, must specify $N - 1$ distances, $N - 2$ angles, and $N - 3$ dihedrals. Typically will converge much faster than Cartesians for small molecules. Implemented in most molecular codes, including GAMESS.

```
$CONTRL COORD=ZMAT NZVAR = 3N-6 $END
```

- Natural internals are generalizations of z-matrix that are coordinates that approximately diagonalize Hessian. Hard to generate *a priori* or automatically. Specification in GAMESS is arcane, done in \$ZMAT.
- Redundant internals are an over-determined set of internal coordinates, like all bond distance, all angles between bonded atoms, all dihedrals. Easily constructed automatically. Mapping between Cartesians and redundant internals becomes more complicated; transform from redundant to Cartesians is overdetermined and has to be solved iteratively. Works very efficiently for molecules though. Implemented (in spirit) in GAMESS.

```
$CONTRL NZVAR = 3N-6 $END
$ZMAT DLC=.TRUE. AUTO=.TRUE. $END
```

	FCH2CH2F	C5H10
Cartesian	13	30
Z-matrix	11	failed
Redundant/DLC	16	failed

6.7 Performance of models for geometries

Generally pretty good! Gross geometries of molecules can be computed with good reliability using common approximations (H-F, LDA, GGA). Subtler things (does FCH₂CH₂F really prefer *trans* or *gauche*?) can take more care in choice of electronic structure model. <https://cccbdb.nist.gov/> is a great place to look for benchmarks.

6.8 Vibrational frequencies

Suppose we are at a minimum on a PES. Near that minimum, we can Taylor expand the PES and truncate at second order (“harmonic”, or quadratic, approximation). The Schrödinger equation describing the dynamical motion of the nuclei can be written in terms of displacements from the equilibrium position, $q_i = x_i - x_i^{\text{eq}}$, $i = 1, \dots, 3N$ and the Hessian H :

$$\hat{H} = -\frac{\hbar^2}{2} \sum_i \frac{1}{m_i} \frac{\partial^2}{dq_i^2} + \frac{1}{2} \sum_{i,j} H_{ij} q_i q_j$$

or in mass-weighted coordinates, $\xi_i = \sqrt{m_i} q_i$:

$$\hat{H} = -\frac{\hbar^2}{2} \sum_i \frac{\partial^2}{d\xi_i^2} + \frac{1}{2} \sum_{i,j} \tilde{H}_{ij} \xi_i \xi_j, \quad \tilde{H}_{ij} = \frac{1}{\sqrt{m_i m_j}} H_{ij}$$

From eigenvalues κ_i and eigenvectors s_i (“normal modes”) of mass-weighted Hessian, can transform into $3N$ one-dimensional problems:

$$\hat{H}_i = -\frac{\hbar^2}{2} \frac{d^2}{ds_i^2} + \kappa_i s_i^2$$

This is one-dimensional harmonic oscillator Hamiltonian, solutions well known.

Table 4: Harmonic oscillator model

$$\begin{aligned}
 V(x) &= \frac{1}{2}\kappa x^2, -\infty < x < \infty \\
 \psi_v(x) &= N_v H_v(x/\alpha) e^{-x^2/2\alpha^2}, v = 0, 1, 2, \dots \\
 \alpha &= (\hbar^2/\kappa)^{1/4}, N_v = (2^v v! \alpha \sqrt{\pi})^{-1/2} \\
 &\text{Hermite polynomials} \\
 H_0(y) &= 1 \\
 H_1(y) &= 2y \\
 H_2(y) &= 4y^2 - 2 \\
 H_{n+1}(y) &= 2yH_n(y) - 2nH_{n-1}(y) \\
 \nu &= \frac{1}{2\pi} \sqrt{\kappa} \\
 E_v &= \left(v + \frac{1}{2}\right) h\nu, v = 0, 1, 2, \dots
 \end{aligned}$$

Do this in $3N$ Cartesian space, so 6 (or 5) of the normal modes correspond to translations and rotations of the molecule. If calculation is exact, these will have $\kappa_i = 0$. Numerical errors may make them somewhat non-zero. If necessary, these can be projected out by transforming Hessian to internal and back to Cartesian coordinates.

Note it is impossible for molecule to just sit at $q = 0$. Nuclei are *always vibrating* about x^{eq} . Gives zero point energy

$$ZPE = \frac{1}{2} \sum_i h\nu_i$$

For a chemical bond, $\kappa \approx 500 \text{ N m}^{-1}$, $h\nu \approx 0.8 \text{ eV}$.

6.8.1 Absorption intensities

Vibrational modes can be probed/observed spectroscopically. Intensity of stimulated absorption from vibrational state i to f given by Einstein coefficient of stimulated absorption:

$$B_{if} = \frac{|\mu_{if}|^2}{6\epsilon_0 \hbar^2}$$

Arises from coupling of electric field of light with dipole of system. Transition dipole moment, μ_{if} given by: $\mu_{if} = \langle \psi_i | \hat{\mu} | \psi_f \rangle$ where $\hat{\mu}$ is dipole operator,

$$\hat{\mu} = \sum q_i \mathbf{r}_i$$

where sum runs over all charged particles and q_i is each charge. Dipole moment changes as molecule vibrates. In direction ξ , can write

$$\hat{\mu}(\xi(t)) = \mu(0) + \xi(t) \left(\frac{d\mu}{d\xi} \right)_{\xi=0} + \dots$$

Use harmonic oscillator wavefunctions for ψ_i and ψ_f :

$$\mu_{if} = \langle \psi_i | \hat{\mu} | \psi_f \rangle = \langle \psi_i | \mu(0) | \psi_f \rangle + \left(\frac{d\mu}{d\xi} \right)_{\xi=0} \langle \psi_i | \xi | \psi_f \rangle + \dots$$

First integral vanishes for $i \neq f$. Second integral provides *gross selection rule* that intensity of transition proportional to the *dynamic* dipole moment along vibrational normal mode ξ and *particular selection rule* that intensity of transition is zero unless $f = i \pm 1$. Latter comes from nature of Hermite polynomials. At normal temperatures, $i = 0$, and the only observable vibrational transitions are $1 \rightarrow 2$.

6.8.2 Performance of harmonic approximation for vibrational spectrum

Harmonic vibrational frequency systematically overestimate experiment. Convolution of *harmonic approximation* error: actual PES is not exactly harmonic, and errors intrinsic to electronic structure model. Errors are typically systematic (see eg <https://doi.org/10.1021/jp960976r>).

	scale factor
HF/3-21G	0.9085
HF/6-31G(d)	0.8929
MP2/6-31G(d)	0.9434
B3LYP/6-31G(d)	0.9613

Relative intensities are generally predicted with good reliability. Model predicts absorption peaks to be delta functions. Peaks always broadened due to a variety of fundamental and instrumental considerations. Common in displaying spectra to arbitrarily broaden using a Lorentzian function.

Figure 10: Scaled HF/6-31G(d) vibrational spectrum vs experiment

6.9 Transition states

6.9.1 Symmetry

Can exploit symmetry to force calculation to converge to a transition state. Eclipsed form of $\text{FCH}_2\text{--CH}_2\text{F}$ has mirror symmetry (C_s), if initialized in that configuration, optimization must preserve symmetry.

6.9.2 Coordinate drag

If reaction state coordinate maps closely onto some internal coordinate, then can do a series of “constrained” optimizations, fixing the coordinate of interest to a series of values and relaxing all other coordinates. Use IFREEZ within GAMESS. For example, define $\text{FCH}_2\text{CH}_2\text{F}$ using z-matrix and freeze F--C--C--F dihedral angle at a series of values.

−277.933 307 329 4 au

$$\Delta E^\ddagger = 0.12 \text{ eV}$$

$$\nu = 154i \text{ cm}^{-1}$$

Coordinate dragging can fail when the reaction coordinate is non-linearly related to the multiple internal coordinates. Plus, it is relatively expensive, as it involves a lot of optimizations.

6.9.3 1st order methods (NEB, ...)

A scan is a first order method that freezes the gradient along a search direction. A better algorithm would use the information along the search direction to find the TS and the entire MEP. That's the spirit of a *nudged elastic band* calculation, for instance. Also of newer methods to generate more sophisticated approximations. Touch on that later...

6.9.4 2nd order methods

Hessian-based methods (like quasi-NR and DIIS) generally work more efficiently, assuming you can find a region reasonably close to the TS and can get a good guess of the Hessian with the appropriate (!) number of negative eigenvalues. These work like regular optimization methods, but search uphill along the negative eigenvector and downhill along the other directions. The Hessian update scheme has to be appropriately modified to accommodate the negative eigenvalue. The choice of coordinate system can become even more crucial.

Algorithm:

1. Identify and optimize structures of reactant and product states
2. Guess a structure for the TS, interpolated either mathematically or empirically between reactant and product

3. Compute initial TS Hessian (RUNTYP = HESSIAN). Only needs to be approximately correct, so appropriate to use a less-expensive method.
4. Confirm Hessian has desired number of imaginary modes, or at least an imaginary mode that maps well onto desired reaction coordinate.
5. Do saddle-point search with guessed Hessian (RUNTYP=SADPOINT, HESS=READ).
6. Check result with final Hessian calculation

6.9.5 Well climbing

Algorithms exist that will climb out of basins and seek transition states....

6.10 Intrinsic reaction coordinates

In more complicated systems, it can often be difficult to know exactly what minima a particular transition state corresponds to. The intrinsic reaction coordinate (IRC) or minimum energy path (MEP) is steepest descent path from TS towards both basins. Starts from TS, steps forward in

direction given by gradient, using second order method. Have to use care in selecting algorithm and step sizes to stay on the path. Can be useful for locating variational transition state. . . configuration where free energy (rather than energy) is maximized.

6.11 Molecular dynamics

Basic idea is to propagate atoms forward in time using some model to compute the forces on atoms and Newton's laws to describe kinetic energy of atoms. May be done at constant energy (*NVE*) or, by coupling kinetic energy to an appropriate reservoir, at constant temperature (*NVT*). Details beyond this course (perhaps beyond this instructor!). Primary point for us is that cost of electronic structure calculations is great enough that typically some adjustments must be made to make force calculations cheap and fast enough to support number of evaluations necessary to do meaningful dynamics.

6.11.1 Cheap parameters

Simplest trick is to back off on the precision and accuracy of calculations to reduce force evaluation cost.

6.11.2 Car-Parrinello dynamics

Treat wavefunction itself as a dynamical variable and propagate forward in time along with the nuclei. Ideally parallels but does not exactly follow Born-Oppenheimer energy surface. Huge advance when originally introduced, has fallen out of favor as more conventional B-O approaches compete more effectively.

6.12 Biased sampling

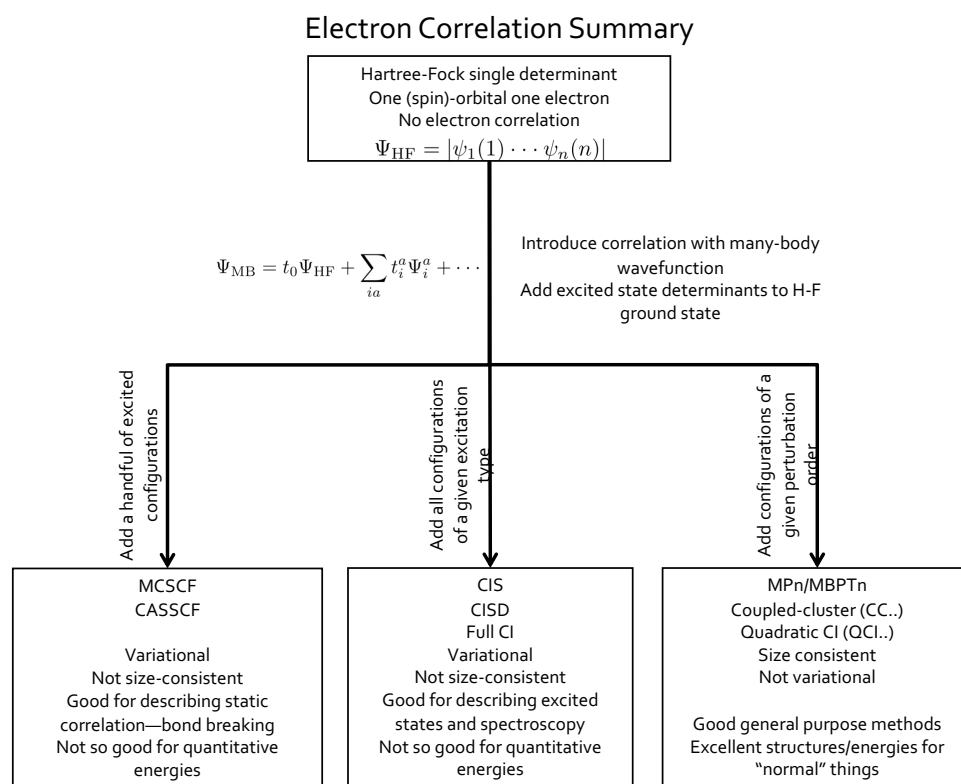

Ask Whitmer. See <https://doi.org/10.1021/acs.jctc.8b00192>.

7 WFT Beyond Hartree-Fock

DFT or WFT calculations of PES's are expensive. Not uncommon to use an heirarcy of methods:

1. Characterize PES using some low-cost model (LDA)
2. Improve structures using some more reliable and expensive method
3. Improve final energies using some even more reliable and expensive method

WFT has the advantage of offering a series of systematically improving models. Starts with Hartree-Fock ground-state wavefunction and build in “many-body” features/electron correlation by combining with “excited” Hartree-Fock wavefunctions:

- static correlation are electron correlation effects that arise from the restrictive form of the H-F wavefunction
- dynamic correlation is like it sounds, the “dance” of all electrons about one another
- configuration interaction is a variational approach to adding in dynamical correlation by combining H-F determinants. Difficult to apply, rarely used any more.
- size consistency is the property that the energy model scales properly with the system size. CI lacks this.
- perturbation theory (MPn) is non-variational, size-consistent, and user-friendly approach

- coupled-cluster (CCxxx) is a systematic, size-consistent approach to introducing H-F correlation. Improvement on perturbation theory.
- quadratic configuration interaction (QCIXxx) is an approximate coupled cluster model.

Heirarcy of models:

$$\text{HF} < \text{MP2} \sim \text{MP3} \sim \text{CCD} < \text{CCSD} < \text{MP4} < \text{CCSD(T)} \sim$$

Reliability also tied to basis set completeness.

		Correlation				
		→				
Basis ↓		HF	MP2	CCSD	CCSD(T) ...	FCI
	SZ					FCI/SZ
	DZ					
	DZP					
	TZ2P				CCSD(T) /TZ2P	FCI/TZ2P
	...					
	Complete basis	HF limit	MP2 limit			exact

“Model chemistry” some linear combination of these, often calibrated against experimental data.
 “G2” most venerable:

	Hartree-Fock	MP2	MP4	QCISD(T)
6-31G(d)	ZPE	Structure		
6-311G(d)		1	2	3
6-311+G(d,p)		4	5	
6-311G(2df,p)		6	7	
6-311+G(3df,p)		8		

$$\text{QCISD(T)}/6\text{-}311\text{+G(3df,p)} \approx 2 + (3 - 2) + (5 - 2) + (7 - 2) + (8 - 1) - (4 - 1) - (6 - 1)$$

$$\Delta E(\text{HLC}) = -2.50 \text{ mHa} * (\text{electron pairs}) - 0.19 \text{ mHa} * (\text{unpaired electrons})$$

$$E(\text{G2}) = \text{QCISD(T)}/6\text{-}311\text{+G(3df,p)} + 0.8929 * \text{ZPE} + \Delta E(\text{HLC})$$

Quality assessed using, eg, mean absolute deviation from some reliable data set. Many elaborations on this same idea in the literature.

8 First-principles thermodynamics

8.1 Connection Between QM and Thermodynamics

8.1.1 Internal energy

The *internal electronic energy* of a single molecule from a WFT/DFT calculation is the energy associated with taking infinitely separated constituent nuclei and electrons at rest and forming a molecule:

Calculate E^{elec} within the Born-Oppenheimer approximation, so the nuclei are fixed in space at the minimum energy configuration.

8.1.2 Zero-point vibrational energy

$$E^0 = E^{\text{elec}} + \text{ZPVE} \quad (48)$$

ZPVE can be calculated reliably within the harmonic approximation, according to

$$\text{ZPVE} = \frac{1}{2} h \sum_{i=1}^{3n-6} \nu_i \quad (49)$$

where ν_i are the harmonic vibrational frequencies, obtained from a vibrational frequency analysis. E^0 is the minimum physically meaningful energy of the molecule.

8.1.3 Finite T energy

Energy can be deposited in a system as translational and rotational kinetic energy, in excited vibrational modes, in the interaction of a molecule with an external electric or magnetic or gravitational field, or If we assume that the energy in these various degrees of freedom are separable, we can write:

$$E_i = E^0 + E^{\text{trans}} + E^{\text{rot}} + E^{\text{vib}} + E^{\text{elec*}} + E^{\text{ext}} \quad (50)$$

To fully describe microscopic energetic state of a system, would have to specify all of these.

Typically want collective properties at equilibrium, like the internal energy U or enthalpy H or Gibbs energy G , under some external constraints like temperature T or volume V . These thermodynamic quantities are averages over the energy states of an *ensemble* of molecules. The way this averaging is performed is the realm of *statistical thermodynamics*.

8.1.4 Canonical ensemble

Free variables are the number of molecules N , the total volume V , and the temperature T . Probability for a molecule to be in some energy state E_i above E^0 is given by the Boltzmann factor,

$$P(E_i) \propto e^{-E_i \beta} = e^{-E_i / k_B T}, \quad \beta = 1 / k_B T \quad (51)$$

Defines an exponentially decaying probability function for a state to be occupied at some temperature. *Temperature* is the characteristic of a system following this distribution.

Probability

8.1.5 Averages and partition functions

Let's use this to calculate the internal energy U of a molecule at some temperature.

$$U(T) = \frac{\sum_i E_i P(E_i)}{\sum_i P(E_i)} \quad (52)$$

where the denominator ensures that the probability is normalized.

$$U(T) = \frac{\sum_i E_i e^{-E_i \beta}}{\sum_i e^{-E_i \beta}} \quad (53)$$

$$= \frac{\frac{\partial}{\partial \beta} \sum_i e^{-E_i \beta}}{\sum_i e^{-E_i \beta}} \quad (54)$$

$$= - \frac{\partial \ln \sum_i e^{-E_i \beta}}{\partial \beta} \quad (55)$$

The sum over energy states is evidently a special quantity, called the partition function:

$$Q = \sum_i e^{-E_i \beta} \quad (56)$$

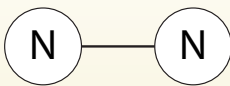

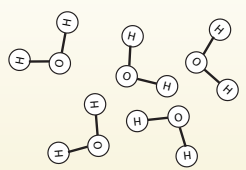

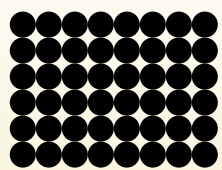

All thermodynamic quantities can be written in terms of the partition function.

Table 5: Equations of the Canonical (NVT) Ensemble

$\beta = 1/k_B T$	Full Ensemble	Distinguishable particles (e.g. atoms in a lattice)	Indistinguishable particles (e.g. molecules in a fluid)
Single particle partition function		$q(V, T) = \sum_i e^{-\epsilon_i \beta}$	$q(V, T) = \sum_i e^{-\epsilon_i \beta}$
Full partition function	$Q(N, V, T) = \sum_j e^{-U_j \beta}$	$Q = q(V, T)^N$	$Q = q(V, T)^N / N!$
Log partition function	$\ln Q$	$N \ln q$	$N \ln q - \ln N!$ $\approx N(\ln q - \ln N + 1)$
Helmholtz energy ($A = U - TS$)	$-\frac{\ln Q}{\beta}$	$-\frac{N \ln q}{\beta}$	$-\frac{N}{\beta} \left(\ln \frac{q}{N} + 1 \right)$
Internal energy (U)	$-\left(\frac{\partial \ln Q}{\partial \beta} \right)_{NV}$	$-N \left(\frac{\partial \ln q}{\partial \beta} \right)_V$	$-N \left(\frac{\partial \ln q}{\partial \beta} \right)_V$
Pressure (P)	$\frac{1}{\beta} \left(\frac{\partial \ln Q}{\partial V} \right)_{N\beta}$	$\frac{N}{\beta} \left(\frac{\partial \ln q}{\partial V} \right)_\beta$	$\frac{N}{\beta} \left(\frac{\partial \ln q}{\partial V} \right)_\beta$
Entropy (S/k_B)	$\beta U + \ln Q$	$\beta U + N \ln q$	$\beta U + N (\ln(q/N) + 1)$
Chemical potential (μ)	$-\frac{1}{\beta} \left(\frac{\partial \ln Q}{\partial N} \right)_{VT}$	$-\frac{\ln q}{\beta}$	$-\frac{\ln(q/N)}{\beta}$

NOTE! All energies are referenced to their values at 0 K. Enthalpy $H = U + PV$, Gibb's Energy $G = A + PV$.

8.2 Stat Mech applied to stuff

Ideal Gas	Bulk Liquid	Macroscopic Solid
		
No intermolecular interactions Only sum over states of individual molecule	Need all inter/intramolecular states, MC/MD to get thermo- dynamic quantities	No rotation or translation. Sum over vibrational modes

8.2.1 Separability

in principle need to sum over all the types of energy states (translational, rotational, vibrational, ...) of every molecule. Seemingly impossible task. One simplification is if we can write energy as sum of energies of individual elements (molecules) of system:

$$E_j = \epsilon_j(1) + \epsilon_j(2) + \dots + \epsilon_j(N) \quad (57)$$

$$Q(N, V, T) = \sum_j e^{-E_j \beta} \quad (58)$$

$$= \sum_j e^{-(\epsilon_j(1) + \epsilon_j(2) + \dots + \epsilon_j(N))\beta} \quad (59)$$

If molecules/elements of system can be distinguished from each other (like atoms in a fixed lattice), expression can be factored:

$$Q(N, V, T) = \left(\sum_j e^{-\epsilon_j(1)\beta} \right) \dots \left(\sum_j e^{-\epsilon_j(N)\beta} \right) \quad (60)$$

$$= q(1) \dots q(N) \quad (61)$$

$$\text{Assuming all the elements are the same:} \quad (62)$$

$$= q^N \quad (63)$$

If *not* distinguishable (like molecules in a liquid or gas, or electrons in a solid), problem is difficult, because identical arrangements of energy amongst elements should only be counted once. Approximate solution, good almost all the time:

$$Q(N, V, T) = q^N / N! \quad (64)$$

Sidebar: “Correct” factoring depends on whether individual elements are fermions or bosons, leads to funny things like superconductivity and superfluidity.

This $q(V, T)$ is the *molecular partition function*, and is calculated by summing over the individual energy states of a single molecule (starting at E_0).

Further simplified by factoring into contributions from various ($3N$) molecular degrees of freedom:

$$q(V, T) = \left(\sum_{\text{trans}} e^{-\epsilon_{\text{trans}} \beta} \right) \left(\sum_{\text{rot}} e^{-\epsilon_{\text{rot}} \beta} \right) \left(\sum_{\text{vib}} e^{-\epsilon_{\text{vib}} \beta} \right) \left(\sum_{\text{elec}} e^{-\epsilon_{\text{elec}} \beta} \right) \quad (65)$$

$$= q_{\text{trans}} q_{\text{rot}} q_{\text{vib}} q_{\text{elec}} \quad (66)$$

$$U = E_0 + U_{\text{trans}} + U_{\text{rot}} + U_{\text{vib}} + U_{\text{elec}} \quad (67)$$

Similarly for other thermodynamic quantities, for example,

$$C_v = \left(\frac{\partial U}{\partial T} \right)_V = C_{v,\text{trans}} + C_{v,\text{rot}} + C_{v,\text{vib}} + C_{v,\text{elec}} \quad (68)$$

Thermodynamic quantities are sums of contributions from individual degrees of freedom.

Have to somehow *model* these motions and have to use our quantum mechanical results to parameterize the models.

8.3 Ideal gas

8.3.1 Ideal gas of molecules

Assume molecules are *indistinguishable* and that internal energy is *seperable*

$$Q_{ig}(N, V, T) = \frac{(q_{\text{trans}} q_{\text{rot}} q_{\text{vib}} q_{\text{elec}})^N}{N!}$$

$$F(N, V, T) = F_{\text{trans}} + F_{\text{rot}} + F_{\text{vib}} + F_{\text{elec}}$$

for any thermodynamic function F .

8.3.2 Electronic partition functions → spin multiplicity

Governed by Fermi-Dirac distribution. Electronic degeneracy at normal T .

8.3.3 Vibrational thermodynamics: harmonic oscillator

Energy spectrum above ZPE given

$$E_v = h\nu v, \quad v = 0, 1, 2, \dots \quad (69)$$

Define characteristic temperature $\Theta = h\nu/k_B$.

$$q(T) = \sum_{v=0}^{\infty} e^{-v(\Theta/T)} \quad (70)$$

$$= \frac{1}{1 - e^{-\Theta/T}} \quad (71)$$

(geometric series). Partition function increasing function of T . Look at limits.

Internal energy:

$$U(T) = - \frac{\partial \ln q}{\partial \beta} \quad (72)$$

$$= \frac{\epsilon_0}{e^{\epsilon_0 \beta} - 1} \quad (73)$$

Need vibrational spectrum to get these contributions.

Results only as good as H-O model! For low frequency modes, errors can be substantial, esp for entropy. Can apply more sophisticated models.

8.3.4 Rotational thermodynamics: rigid rotor

Characteristic temperature $\Theta_{\text{rot}} = \hbar^2/2Ik_B$. Moment of inertia I only depends on shape or molecule—geometry optimization.

“High” T $q_{\text{rot}}(T) \approx \sigma\Theta_{\text{rot}}/T$, most often true

8.3.5 Translational states: particle-in-a-box

$$E_n = \frac{n^2\pi^2\hbar^2}{2mL^2} = \epsilon_0 n^2, \quad n = 1, 2, 3, \dots$$

$\Theta_{\text{trans}} = \epsilon_0/k_B$ is typically tiny, allows partition function sum to be approximated by integral:

$$q_{\text{trans,1D}} \approx \int_0^\infty e^{-x^2\beta\epsilon_0} dx = L/\Lambda$$

$$\Lambda = \frac{h}{\sqrt{2\pi m k_B T}} \quad \text{thermal wavelength}$$

$$q_{\text{trans,3D}} = V/\Lambda^3$$

Thermal wavelength Λ depends only a molecule mass and is of the order the box dimensions at which quantization is evident. Typically a tiny number (eg 1.7×10^{-11} m for Ar in a 1 L volume at 298 K. q_{trans} is thus enormous: lots of translational freedom. q depends on volume, introduces volume/concentration/pressure dependence into thermo functions. Conventional to define a *standard state* V° volume, or corresponding pressure.

8.4 Chemical reactions and equilibria

8.4.1 Chemical reaction

1. General chemical reaction $\sum_i \nu_i A_i = 0$, ν_i stoichiometric coefficients
2. Thermodynamic change $\Delta W^\circ(T) = \sum_i \nu_i W_i^\circ(T)$, where $W = A, U, S, G, \dots$
3. “Standard state” derives from concentration dependence of entropy
4. “Standard state” corresponds to some standard choice, $(N/V)^\circ = c^\circ$, e.g. 1 mol/l (T-independent), or $(N/V)^\circ = P^\circ/RT$, e.g. 1 bar (T-dependent)
5. Permits functions to be easily computed at other concentrations, e.g.

$$A(T, N/V) = A^\circ(T) + kT \ln((N/V)/(N/V)^\circ) = A^\circ(T) + kT \ln(c/c^\circ)$$

6. Example: ethane dehydrogenation, $\text{C}_2\text{H}_6 \longrightarrow \text{C}_2\text{H}_4 + \text{H}_2$, 1 bar standard state
7. Reaction entropy captures contributions of all degrees of freedom
8. Reaction energy (internal, Helmholtz, ...) must *also* capture difference in 0 K electronic energy

$$\Delta U^\circ(T) = U_B^\circ(T) - U_A^\circ(T) + \Delta E(0)$$

Table 6: Statistical Thermodynamics of an Ideal Gas**Translational DOFs** 3-D particle in a box model

$$\theta_{\text{trans}} = \frac{\pi^2 \hbar^2}{2mL^2 k_B}, \quad \Lambda = h \left(\frac{\beta}{2\pi m} \right)^{1/2}$$

For $T \gg \Theta_{\text{trans}}$, $\Lambda \ll L$, $q_{\text{trans}} = V/\Lambda^3$ (essentially always true)

$$U_{\text{trans}} = \frac{3}{2}RT \quad C_{v,\text{trans}} = \frac{3}{2}R \quad S_{\text{trans}}^\circ = R \ln \left(\frac{e^{5/2} V^\circ}{N^\circ \Lambda^3} \right) = R \ln \left(\frac{e^{5/2} k_B T}{P^\circ \Lambda^3} \right)$$

Rotational DOFs Rigid rotor model**Linear molecule** $\theta_{\text{rot}} = hcB/k_B$

$$q_{\text{rot}} = \frac{1}{\sigma} \sum_{l=0}^{\infty} (2l+1) e^{-l(l+1)\theta_{\text{rot}}/T}, \approx \frac{1}{\sigma} \frac{T}{\theta_{\text{rot}}}, \quad T \gg \theta_{\text{rot}} \quad \sigma = \begin{cases} 1, & \text{unsymmetric} \\ 2, & \text{symmetric} \end{cases}$$

$$U_{\text{rot}} = RT \quad C_{v,\text{rot}} = R \quad S_{\text{rot}}^\circ = R(1 - \ln(\sigma \theta_{\text{rot}}/T))$$

Non-linear molecule $\theta_{\text{rot},\alpha} = hcB_\alpha/k_B$

$$q_{\text{rot}} \approx \frac{1}{\sigma} \left(\frac{\pi T^3}{\theta_{\text{rot},\alpha} \theta_{\text{rot},\beta} \theta_{\text{rot},\gamma}} \right)^{1/2}, \quad T \gg \theta_{\text{rot},\alpha,\beta,\gamma} \quad \sigma = \text{rotational symmetry number}$$

$$U_{\text{rot}} = \frac{3}{2}RT \quad C_{v,\text{rot}} = \frac{3}{2}R \quad S_{\text{rot}}^\circ = \frac{R}{2} \left(3 - \ln \frac{\sigma \theta_{\text{rot},\alpha} \theta_{\text{rot},\beta} \theta_{\text{rot},\gamma}}{\pi T^3} \right)$$

Vibrational DOFs Harmonic oscillator model**Single harmonic mode** $\theta_{\text{vib}} = h\nu/k_B$

$$q_{\text{vib}} = \frac{1}{1 - e^{-\theta_{\text{vib}}/T}} \approx \frac{T}{\theta_{\text{vib}}}, \quad T \gg \theta_{\text{vib}}$$

$$U_{\text{vib}} = \frac{R \theta_{\text{vib}}}{e^{\theta_{\text{vib}}/T} - 1} \quad C_{v,\text{vib}} = R \left(\frac{\theta_{\text{vib}}}{T} \frac{e^{\theta_{\text{vib}}/2T}}{e^{\theta_{\text{vib}}/T} - 1} \right)^2 \quad S_{\text{vib},i}^\circ = R \left(\frac{\theta_{\text{vib}}/T}{e^{\theta_{\text{vib}}/T} - 1} - \ln(1 - e^{-\theta_{\text{vib}}/T}) \right)$$

Multiple harmonic modes $\theta_{\text{vib},i} = h\nu_i/k_B$

$$q_{\text{vib}} = \prod_i \frac{1}{1 - e^{-\theta_{\text{vib},i}/T}}$$

$$U_{\text{vib}} = R \sum_i \frac{\theta_{\text{vib},i}}{e^{\theta_{\text{vib},i}/T} - 1} \quad C_{v,\text{vib}} = R \sum_i \left(\frac{\theta_{\text{vib},i}}{T} \frac{e^{\theta_{\text{vib},i}/2T}}{e^{\theta_{\text{vib},i}/T} - 1} \right)^2 \quad S_{\text{vib},i}^\circ = R \left(\frac{\theta_{\text{vib},i}/T}{e^{\theta_{\text{vib},i}/T} - 1} - \ln(1 - e^{-\theta_{\text{vib},i}/T}) \right)$$

Electronic DOFs $q_{\text{elec}} = \text{spin multiplicity}$

Table 7: Contributions to ideal gas thermodynamics

	Characteristic Energy (cm ⁻¹)	Characteristic Temperature (K)	States @ RT	
translational	$\hbar^2/2mL^2 \approx 10^{-21}$	10^{-21}	10^{30}	classical limit
rotational	≈ 1	≈ 1	100's	semi-classical
vibrational	≈ 1000	≈ 1000	1	non-classical
electronic	$\approx 10,000$	$\approx 10,000$	1	non-classical

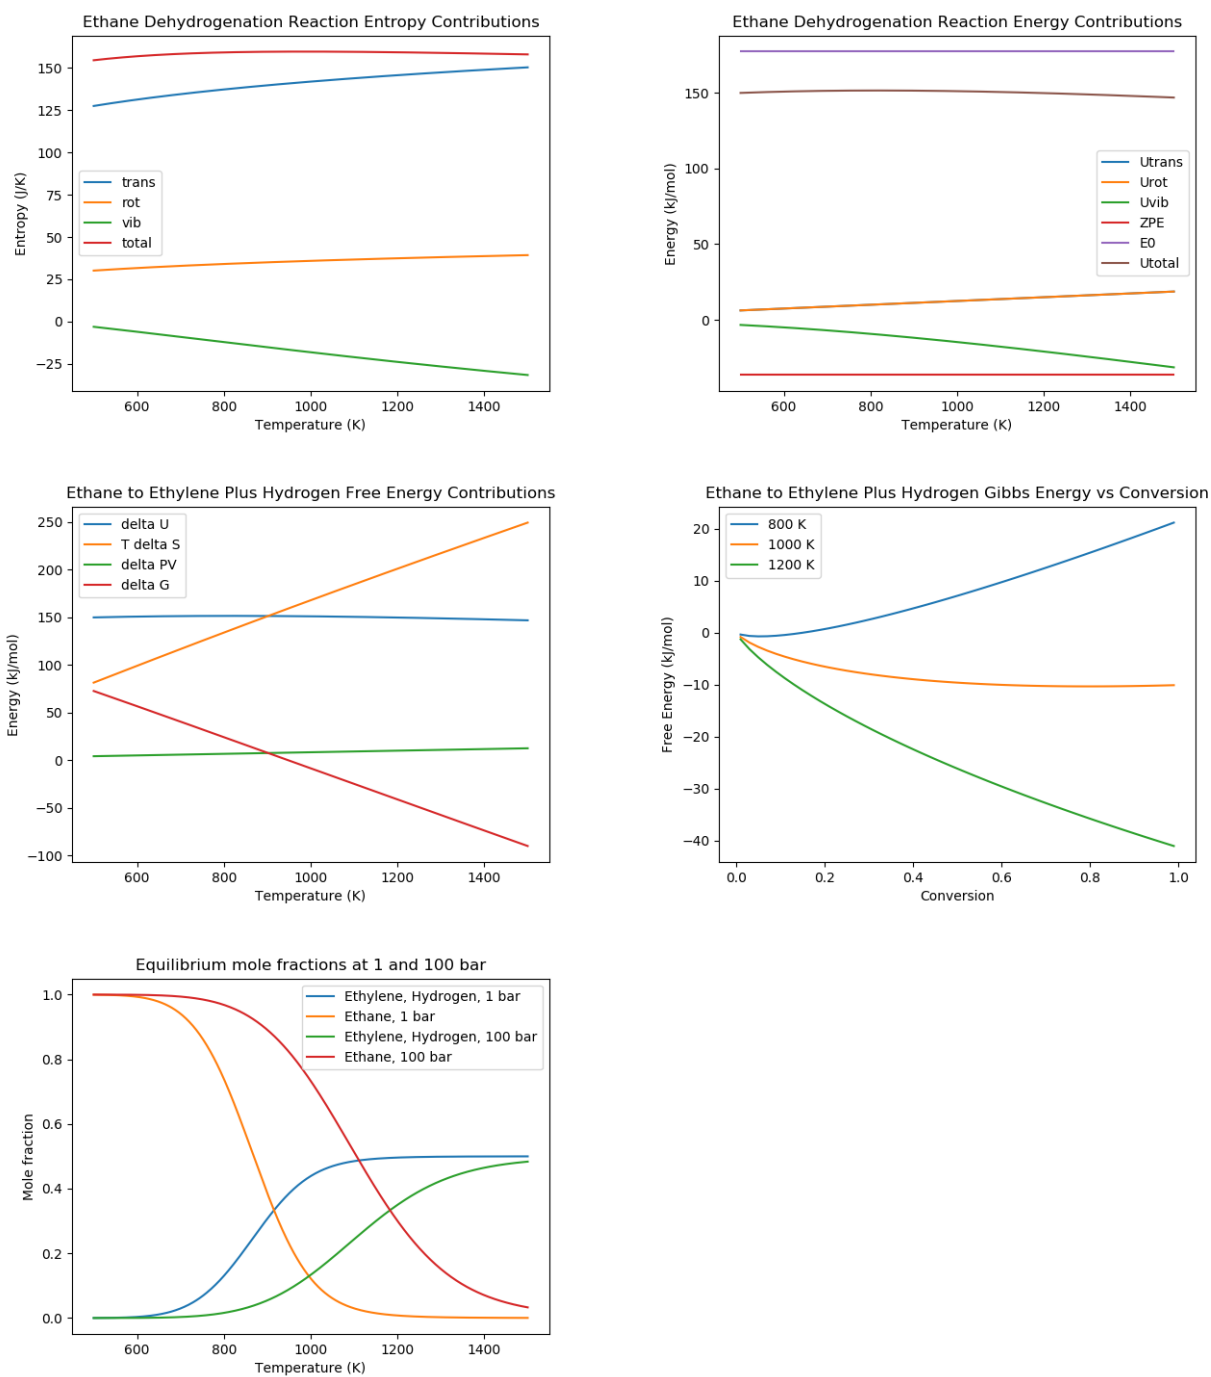

Table 8: Ethane thermodynamics

Table 9: Ethane to ethylene plus hydrogen standard state (1 bar) thermodynamics

8.4.2 Chemical equilibrium

1. At chemical equilibrium, total free energy minimized with respect to reaction advancement ξ

$$G(T, \xi) = \xi(\Delta G^\circ + kT \sum_i \nu_i \ln P_i/P^\circ)$$

2. Equilibrium condition—equate chemical potentials

$$\begin{aligned} \mu_A(N, V, T) &= \mu_B(N, V, T) \\ E_A(0) - kT \ln(q_A/N_A) &= E_B(0) - kT \ln(q_B/N_B) \\ \frac{N_B}{N_A} = \frac{N_B/V}{N_A/V} &= \frac{q_B(T, V)/V}{q_A(T, V)/V} e^{-\Delta E(0)/kT} \end{aligned}$$

3. $q/V = 1/\Lambda^3$ has units of number/volume, or concentration
4. Equilibrium constant—convert units to some standard concentration c° or pressure P°

$$\begin{aligned} q_A^\circ(T) &= (q_A(T, V)/V)(1/c^\circ) \\ q_A^\circ(T) &= (q_A(T, V)/V)(RT/P^\circ) \\ K_{eq}(T) &= \frac{q_B^\circ(T)}{q_A^\circ(T)} e^{-\Delta E(0)/kT} = e^{-\Delta G^\circ(T)/kT} \end{aligned}$$

8.5 Reaction rates

Rate: number per unit time per unit something (volume, area, ...). Reactions hypothesized to occur through sequence of elementary steps.

For example, ozone decomposition, rate second-order at high P_{O_2} , first-order at low P_{O_2}

See two compute rates of individual steps.

8.5.1 Transition state theory (TST)

1. Assumptions
 - (a) Existence of reaction coordinate (PES)
 - (b) Existence of dividing surface
 - (c) Equilibrium between reactants and “transition state”
 - (d) Harmonic approximation for transition state

- rate proportional to concentration of “activated complex” over reactants times crossing frequency

$$\begin{aligned}
 r &= k C_A C_B \\
 &= k^\ddagger C_{AB}^\ddagger \\
 &= \nu^\ddagger K^\ddagger C_A C_B \\
 &= \nu^\ddagger \frac{k_B T}{h \nu^\ddagger} \bar{K}^\ddagger(T) C_A C_B \\
 &= \frac{k_B T}{h} \frac{q^\ddagger(T)}{q_A(T) q_B(T)} e^{-\Delta E(0)/k_B T} C_A C_B
 \end{aligned}$$

- application to two molecules - vinyl alcohol to acetaldehyde
- microscopic reversibility
- equilibrium requirement $K_{eq}(T) = k_f(T)/k_r(T)$

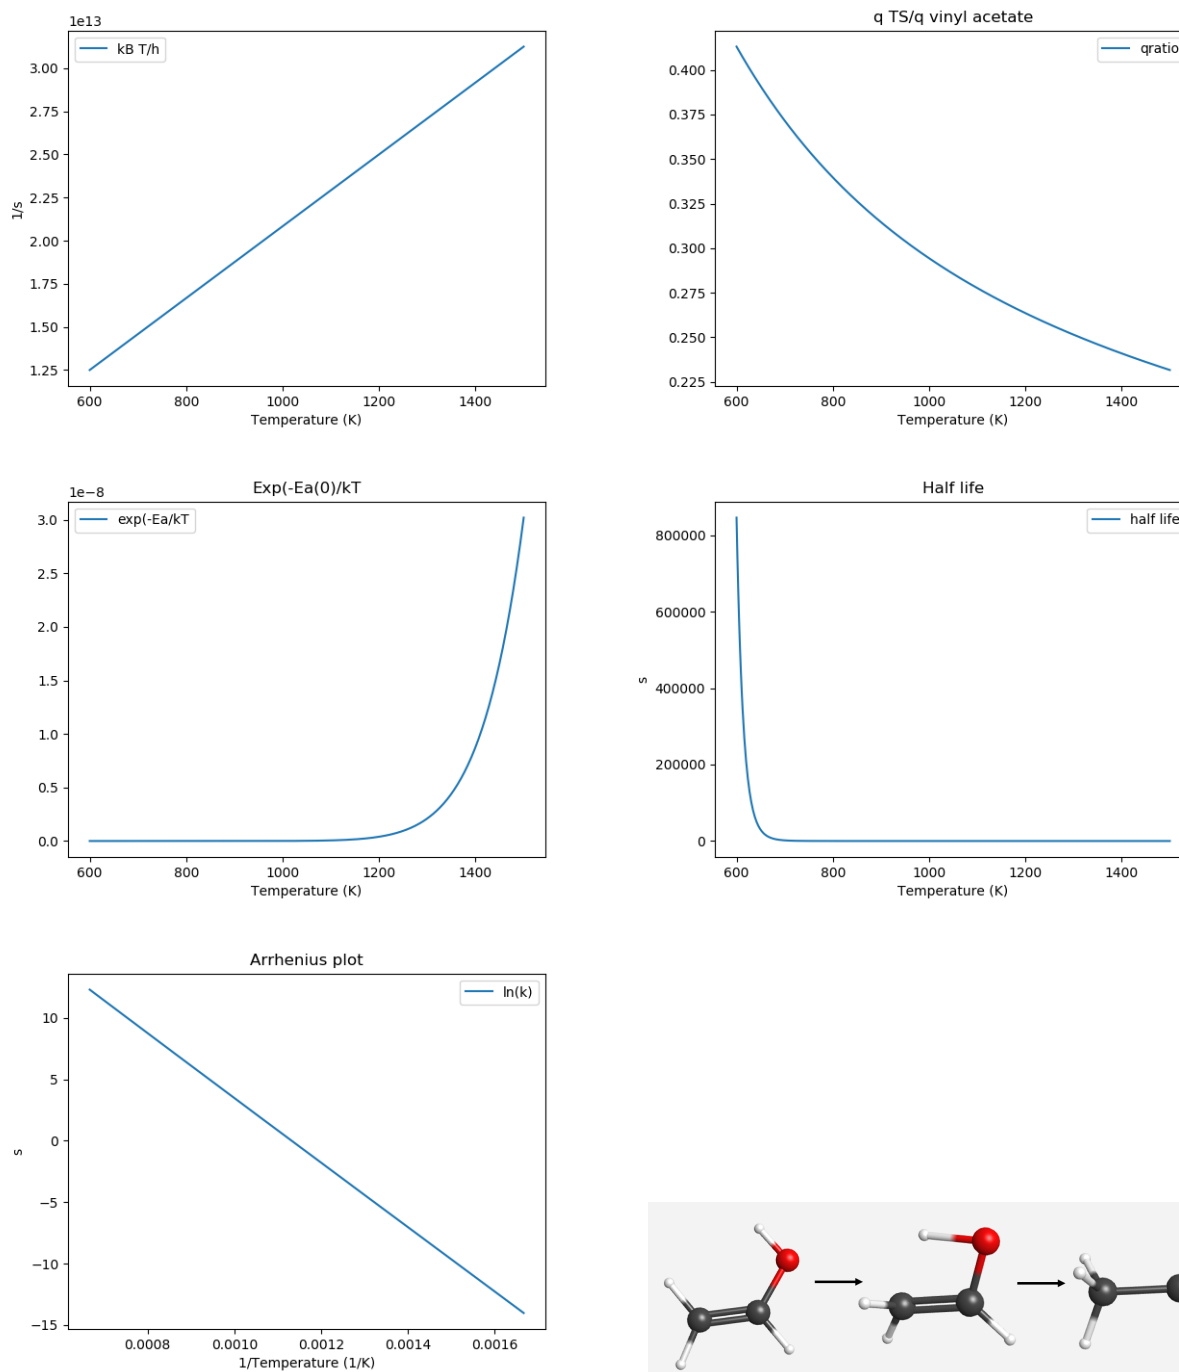

8.5.2 Thermodynamic connection

- Relate activated complex equilibrium constant to activation free energy

$$\bar{K}^\ddagger(T) = e^{-\Delta G^{\circ\ddagger}(T)/kT} = e^{-\Delta H^{\circ\ddagger}(T)/k_B T} e^{\Delta S^{\circ\ddagger}(T)/k_B T}$$

- Compare to Arrhenius expression

$$E_a = \Delta H^{\circ\ddagger}(T) + kT, A = \frac{k_B T}{h} e^1 e^{\Delta S^{\circ\ddagger}(T)/k_B T}$$

Table 10: Vinyl alcohol to acetaldehyde

9 Plane waves and core potentials

9.1 Periodic boundary conditions

Free particle moving in one dimension

$$\phi_G(x) = e^{iGx}$$

G can take any value. Eigenfunction of momentum and kinetic energy operators. In particular,

$$E_G = \frac{\hbar^2}{2m} G^2$$

Suppose we impose *periodic boundary conditions*, so that $\phi_G(x) = \phi_G(x + na)$, $n = \pm 1, \dots$ a is a lattice vector.

$$e^{iGx} = e^{iG(x+a)} \rightarrow e^{iGa} = 1$$

Places constraints on G :

$$G = \frac{2\pi}{a}n, n = \pm 1, \dots$$

$2\pi/a$ is a reciprocal lattice vector.

Normalized on domain a ,

$$\phi_G(x) = \frac{1}{\sqrt{a}} e^{iGx}$$

Properties of these plane wave functions:

1. Periodic, $\lambda_G = a/n$
2. Orthonormal, $\langle \phi_G | \phi_{G'} \rangle = \delta_{G,G'}$
3. Definite kinetic energy
4. Complete

$$\psi(x) = \sum_G \phi_G(x) \langle \phi_G | \psi \rangle \quad (74)$$

$$= \sum_G \phi_G(x) \psi(G) \quad (75)$$

$\psi(G)$ is Fourier transform of $\psi(x)$. Both contain exactly the same information. Can take advantage of Fourier transform machinery to transform between two representations. For general function $\psi(x)$, represent on some grid of size N . Size of grid determined by maximum frequency/minimum wavelength included. $N \log(N)$ operations to transform back and forth.

Integrals can be evaluated in either x or G space:

$$I = \int_a A^*(x) B(x) dx \quad (76)$$

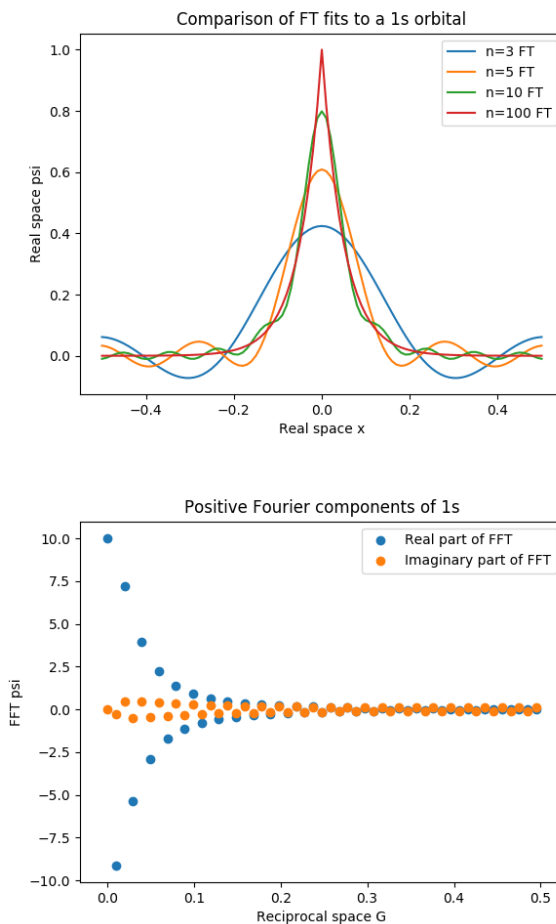

$$= \sum_{G,G'} A^*(G) B(G) \int e^{-iGx} e^{iG'x} dx \quad (77)$$

$$= \sum_{G,G'} A^*(G) B(G) \delta_{G,G'} \quad (78)$$

$$= a \sum_G A^*(G) B(G) \quad (79)$$

Can leverage to simplify solving any problems that are periodic.

9.2 Example

9.3 Hydrogen atom in a box

Suppose we place an atom at some point R in each box. In principle, can represent solutions as linear combinations of plane waves. Plane waves become basis functions.

Does where we put the atom matter to the answer? No. Always related by structure factor.

In principle, would have to let G run to infinity to have complete basis. In practice, would have to cut off at some point, defined by

$$\frac{\hbar^2}{2m_e} G^2 < \frac{\hbar^2}{2m_e} G_{\text{cut}}^2 = E_{\text{cutoff}}$$

Sets minimum wavelength retained in basis, and thus size of basis. For fixed E_{cutoff} , larger a implies larger basis. Basis size has to be a whole number, so changes discontinuously with E_{cutoff} .

Recall our basic equation

$$\left\{ \hat{h} + v_{\text{Coulomb}}[\rho] + v_{\text{exchange}}[\psi_i] + v_{\text{correlation}}[\psi_i] \right\} \psi_i(\mathbf{r}) = \epsilon_i \psi_i(\mathbf{r}) \quad (80)$$

Contains kinetic and potential energy terms.

Kinetic energy is diagonal in plane wave basis... easy!

$$\langle \phi_G | -\frac{1}{2} \frac{d^2}{dx^2} | \phi_{G'} \rangle = \frac{1}{2} G^2 \delta_{G,G'}$$

Potential energy terms can take advantage of Fourier transforms.

$$v(x) = \sum_{G''} v(G'') e^{iG''x} \quad (81)$$

$$\langle \phi_G | v(x) | \phi_{G'} \rangle = \sum_{G''} v(G'') \langle \phi_G | \phi_{G''} | \phi_{G'} \rangle \quad (82)$$

$$= v(G' - G) \quad (83)$$

How many Fourier components to include in the sums? Turns out for a basis of dimension m you need $2m$ components to specify the potential exactly, but you can generally get away with smaller. The cost and accuracy of the calculation scale with this choice.

Solutions given by $\psi_i(x) = \sum_G c_i(G) \phi_G(x)$.

One key thing we would need to evaluate potentials is electron density, $\rho(x)$. Let f_i be occupancy of each orbital.

$$\rho(x) = \sum_i f_i |\psi_i(x)|^2 \quad (84)$$

$$= \frac{1}{a} \sum_i f_i \sum_{G,G'} c_i^*(G) c_i(G') e^{i(G-G')x} \quad (85)$$

$$= \sum_{-2G_{\max}}^{2G_{\max}} n(G) e^{iGx} \quad (86)$$

Electron density exactly represented in plane wave basis with cutoff four times that of the basis set cutoff.

9.4 Three-dimensional periodicity

Same ideas generalize to three dimensional periodicity.

Lattice constants of periodic cell become three vectors, $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$. As we'll discuss a little bit later, these vectors will be from one of the Bravais lattices. Every point \mathbf{R} is equivalent to any other point $\mathbf{R}' = \mathbf{R} + n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2 + n_3 \mathbf{a}_3$.

Periodic box matrix $\mathbf{h} = [\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3]$. Periodic box volume $\Omega = \det \mathbf{h}$.

Reciprocal lattice defined such that $\mathbf{b}_i \cdot \mathbf{a}_j = 2\pi \delta_{ij}$. Given by

$$2\pi(\mathbf{h}^t)^{-1} = [\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3]$$

Reciprocal lattice vectors become $\mathbf{G} = i\mathbf{b}_1 + j\mathbf{b}_2 + k\mathbf{b}_3$. Basis functions become $\phi(\mathbf{r}) = \frac{1}{\Omega} e^{i\mathbf{G} \cdot \mathbf{r}}$.

Locations of atoms \mathbf{R}_α within this periodic cell can be specified in Cartesians or as fractional coordinates of the lattice vectors. Related by $\mathbf{R}_\alpha = \mathbf{h} \mathbf{f}$.

In general, can use this periodic representation to describe atoms, molecules, whatever. If we want to describe isolated things, box dimensions must be large enough to avoid artificial interactions between periodic images.

In particular, Coulomb potentials decay like $1/r$ and are thus long-ranged. Have to use special tricks (Ewald sums) to evaluate these sums, and have to carefully group electrostatic terms to avoid non-convergent sums.

Key limitations:

1. Periodic cell must be charge-neutral. The electrostatic energy of an infinite, charged system diverges.
2. Supercell must not have a net electric field.
3. The absolute electrostatic potential is not well-defined (there is no “vacuum” to reference the energy of an electron to).

These limitations can be overcome to some extent by applying artificial backgrounds.

9.5 SCF

Same essential idea. Guess initial charge density and set of orbital coefficients. Iterate to self-consistency.

14.4 Hohenberg-Kohn theorems

14.5 Kohn-Sham construction

14.6 Exchange-correlation functionals

So Kohn et al. showed that the DFT approach is theoretically well-grounded and provided one way to practically apply it. Promise is that if we can find an approximation to the (unknown) true v_{xc} with the right balance of simplicity and accuracy, we will have one sweet theory. Has to incorporate both exchange, like Slater tried to do, and correlation.

How to proceed? Lots of approaches, and jargon here is at least as bad as in wavefunction-based methods. Perdew 2006 describes the “Jacob’s ladder” of approximations:

14.6.1 LDA

One well-defined limit is the homogeneous electron gas, and this is the usual starting point for modern approximate DFT methods. Assume exchange and correlation potentials at any given point depend only on the value of ρ there (or spin-up and spin-down ρ , if spin-polarized). We know from Slater and Dirac’s work what the exchange potential is for this system.

It is possible to determine numerically the correlation energy for a given density from quantum Monte Carlo calculations. Ceperley and Alder (PRL 1980, 45, 566) did this to very high accuracy, and others (Vosko, Wilk, and Nusair, “VWN”, and Perdew and Wang, “PW”) fit these numerical results to analytical models in ρ . This combination of local exchange and correlation defines the LDA model.

LDA offers modest improvement over HFS for molecules. “Homogeneous” approximation pretty severe for an atom or molecule. Nonetheless, works surprisingly well for structures and charge distributions, but has problems in calculating accurate bond energies, typically overbinding. Also tends to underestimate the HOMO-LUMO gap in molecules and analogous band gap in solids.
